Shaft compression load test data should be extrapolated to production shafts that are not load tested as specified in Article 10.8.3.5.6. There is no way to verify shaft resistance for the untested production shafts, other than through good construction inspection and visual observation of the soil or rock encountered in each shaft. Because of this, extrapolation of the shaft load test results to the untested production shafts may introduce some uncertainty. Statistical data are not available to quantify this at this time. Historically, resistance factors higher than 0.70, or their equivalent safety factor in previous practice, have not been used for shaft foundations. If the recommendations in Paikowsky et al. (2004) are used to establish a resistance factor when shaft static load tests are conducted, in consideration of site variability, the resistance factors recommended by Paikowsky et al. for this case should be reduced by 0.05, and should be less than or equal to 0.70 as specified in Table 10.5.5.2.4-1.

This issue of uncertainty in how the load test is applied to shafts not load tested is even more acute for shafts subjected to uplift load tests, as failure in uplift can be more abrupt than failure in compression. Hence, a resistance factor of 0.60 for the use of uplift load test results is recommended.

**Table 10.5.5.2.4-1—Resistance Factors for Geotechnical Resistance of Drilled Shafts**

| Method/Soil/Condition | | | Resistance Factor |
|---|---|---|---|
| Nominal Axial Compressive Resistance of Single-Drilled Shafts, $\varphi_{stat}$ | Side resistance in clay | α-method (Brown et al., 2010) | 0.45 |
| | Tip resistance in clay | Total Stress (Brown et al., 2010) | 0.40 |
| | Side resistance in sand | β-method (Brown et al., 2010) | 0.55 |
| | Tip resistance in sand | Brown et al. (2010) | 0.50 |
| | Side resistance in cohesive IGMs | Brown et al. (2010) | 0.60 |
| | Tip resistance in cohesive IGMs | Brown et al. (2010) | 0.55 |
| | Side resistance in rock | Kulhawy et al. (2005)<br>Brown et al. (2010) | 0.55 |
| | Side resistance in rock | Carter and Kulhawy (1988) | 0.50 |
| | Tip resistance in rock | Canadian Geotechnical Society (1985)<br>Pressuremeter Method (Canadian Geotechnical Society, 1985)<br>Brown et al. (2010) | 0.50 |
| Block Failure, $\varphi_{b1}$ | Clay | | 0.55 |
| Uplift Resistance of Single-Drilled Shafts, $\varphi_{up}$ | Clay | α-method (Brown et al., 2010) | 0.35 |
| | Sand | β-method (Brown et al., 2010) | 0.45 |
| | Rock | Kulhawy et al. (2005)<br>Brown et al. (2010) | 0.40 |
| Group Uplift Resistance, $\varphi_{ug}$ | Sand and clay | | 0.45 |
| Horizontal Geotechnical Resistance of Single Shaft or Shaft Group | All materials | | 1.0 |
| Static Load Test (compression), $\varphi_{load}$ | All Materials | | 0.70 |
| Static Load Test (uplift), $\varphi_{upload}$ | All Materials | | 0.60 |

*10.5.5.2.5—Micropiles*

Resistance factors shall be selected from Table 10.5.5.2.5-1 based on the method used for determining the nominal axial pile resistance. If the resistance factors provided in Table 10.5.5.2.5-1 are to be applied to piles in potentially creeping soils, highly plastic soils, weak rock, or other marginal ground type, the resistance factor values in the Table should be reduced by 20 percent to reflect greater design uncertainty.

*C10.5.5.2.5*

The resistance factors in Table 10.5.5.2.5-1 were calibrated by fitting to ASD procedures tempered with engineering judgment. The resistance factors in Table 10.5.5.2.5-2 for structural resistance were calibrated by fitting to ASD procedures and are equal to or slightly more conservative than corresponding resistance factors from Section 5 of the *AASHTO LRFD Bridge Design Specifications* for reinforced concrete column design.

**Table 10.5.5.2.5-1—Resistance Factors for Geotechnical Resistance of Axially Loaded Micropiles**

| Limit State | Method/ Ground Condition | Resistance Factor |
|---|---|---|
| Compression Resistance of Single Micropile, $\phi_{stat}$ | Side Resistance (Bond Resistance): Presumptive Values | 0.55(1) |
| | Tip Resistance on Rock O'Neill and Reese (1999) | 0.50 |
| | Side Resistance and Tip Resistance Load Test | Values in Table 10.5.5.2.3-1, but no greater than 0.70 |
| Block Failure, $\phi_{bl}$ | Clay | 0.60 |
| Uplift Resistance of Single Micropile, $\phi_{up}$ | Presumptive Values | 0.55(1) |
| | Tension Load Test | Values in Table 10.5.5.2.3-1, but no greater than 0.70 |
| Group Uplift Resistance, $\phi_{ug}$ | Sand & Clay | 0.50 |

(1) Apply to presumptive grout-to-ground bond values for preliminary design only in Article C10.9.3.5.2.

**Table 10.5.5.2.5-2—Resistance Factors for Structural Resistance of Axially Loaded Micropiles**

| Section/Loading Condition | | Resistance Factor |
|---|---|---|
| Pile Cased Length | Tension, $\varphi_{TC}$ | 0.80 |
| | Compression, $\varphi_{CC}$ | 0.75 |
| Pile Uncased Length | Tension, $\varphi_{TU}$ | 0.80 |
| | Compression, $\varphi_{CU}$ | 0.75 |

### 10.5.5.3—Extreme Limit States

*10.5.5.3.1—General*

Design of foundations at extreme limit states shall be consistent with the expectation that structure collapse is prevented and that life safety is protected.

*10.5.5.3.2—Scour*

The provisions of Articles 2.6.4.4.2 and 3.7.5 shall apply to the changed foundation conditions resulting from scour. Resistance factors at the strength limit state shall be taken as specified herein. Resistance factors at the extreme event shall be taken as 1.0 except that for uplift resistance of piles and shafts, the resistance factor shall be taken as 0.80 or less.

The foundation shall resist not only the loads applied from the structure but also any debris loads occurring during the flood event.

*C10.5.5.3.2*

The specified resistance factors should be used provided that the method used to compute the nominal resistance does not exhibit bias that is unconservative. See Paikowsky et al. (2004) regarding bias values for pile resistance prediction methods.

Design for scour is discussed in Hannigan et al. (2005).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.5.5.3.3—Other Extreme Limit States*

Resistance factors for extreme limit state, including the design of foundations to resist earthquake, ice, vehicle or vessel impact loads, shall be taken as 1.0. For uplift resistance of piles and shafts, the resistance factor shall be taken as 0.80 or less.

*C10.5.5.3.3*

The difference between compression skin friction and tension skin friction should be taken into account through the resistance factor, to be consistent with how this is done for the strength limit state (see Article 10.5.5.2.3).

## 10.6—SPREAD FOOTINGS

### 10.6.1—General Considerations

#### 10.6.1.1—General

Provisions of this Article shall apply to design of isolated, continuous strip and combined footings for use in support of columns, walls and other substructure and superstructure elements. Special attention shall be given to footings on fill, to make sure that the quality of the fill placed below the footing is well controlled and of adequate quality in terms of shear strength and compressibility to support the footing loads.

Spread footings shall be proportioned and designed such that the supporting soil or rock provides adequate nominal resistance, considering both the potential for adequate bearing strength and the potential for settlement, under all applicable limit states in accordance with the provisions of this Section.

Spread footings shall be proportioned and located to maintain stability under all applicable limit states, considering the potential for, but not necessarily limited to, overturning (eccentricity), sliding, uplift, overall stability and loss of lateral support.

#### C10.6.1.1

Problems with insufficient bearing and/or excessive settlements in fill can be significant, particularly if poor, e.g., soft, wet, frozen, or nondurable, material is used, or if the material is not properly compacted.

Spread footings should not be used on soil or rock conditions that are determined to be too soft or weak to support the design loads without excessive movement or loss of stability. Alternatively, the unsuitable material can be removed and replaced with suitable and properly compacted engineered fill material, or improved in place, at reasonable cost as compared to other foundation support alternatives.

Footings should be proportioned so that the stress under the footing is as nearly uniform as practicable at the service limit state. The distribution of soil stress should be consistent with properties of the soil or rock and the structure and with established principles of soil and rock mechanics.

#### 10.6.1.2—Bearing Depth

Where the potential for scour, erosion or undermining exists, spread footings shall be located to bear below the maximum anticipated depth of scour, erosion, or undermining as specified in Article 2.6.4.4.

#### C10.6.1.2

Consideration should be given to the use of either a geotextile or graded granular filter material to reduce the susceptibility of fine grained material piping into rip rap or open-graded granular foundation material.

For spread footings founded on excavated or blasted rock, attention should be paid to the effect of excavation and/or blasting. Blasting of highly resistant competent rock formations may result in overbreak and fracturing of the rock to some depth below the bearing elevation. Blasting may reduce the resistance to scour within the zone of overbreak or fracturing.

Evaluation of seepage forces and hydraulic gradients should be performed as part of the design of foundations that will extend below the groundwater table. Upward seepage forces in the bottom of excavations can result in piping loss of soil and/or heaving and loss of stability in the base of foundation excavations. Dewatering with wells or wellpoints can control these problems. Dewatering can result in settlement of adjacent ground or structures. If adjacent structures may be damaged by settlement induced by dewatering, seepage cut-off methods such as sheet piling or slurry walls may be necessary.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Spread footings shall be located below the depth of frost potential. Depth of frost potential shall be determined on the basis of local or regional frost penetration data.

Consideration may be given to over-excavation of frost susceptible material to below the frost depth and replacement with material that is not frost susceptible.

### 10.6.1.3—Effective Footing Dimensions

For eccentrically loaded footings, a reduced effective area, $B' \times L'$, within the confines of the physical footing shall be used in geotechnical design for settlement or bearing resistance. The point of load application shall be at the centroid of the reduced effective area.

The reduced dimensions for an eccentrically loaded rectangular footing shall be taken as:

$$B' = B - 2e_B \qquad (10.6.1.3\text{-}1)$$

$$L' = L - 2e_L$$

where:

$e_B$ = eccentricity parallel to dimension $B$ (ft)
$e_L$ = eccentricity parallel to dimension $L$ (ft)

Footings under eccentric loads shall be designed to ensure that the factored bearing resistance is not less than the effects of factored loads at all applicable limit states.

For footings that are not rectangular, similar procedures should be used based upon the principles specified above.

### C10.6.1.3

The reduced dimensions for a rectangular footing are shown in Figure C10.6.1.3-1.

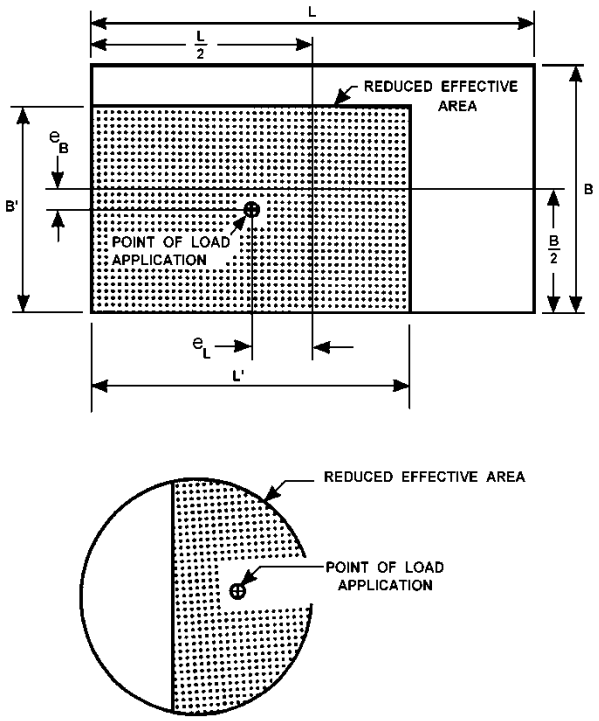

**Figure C10.6.1.3-1—Reduced Footing Dimensions**

For footings that are not rectangular, such as the circular footing shown in Figure C10.6.1.3-1, the reduced effective area is always concentrically loaded and can be estimated by approximation and judgment. Such an approximation could be made, assuming a reduced rectangular footing size having the same area and centroid as the shaded area of the circular footing shown in Figure C10.6.1.3-1.

### 10.6.1.4—Bearing Stress Distributions

When proportioning footing dimensions to meet settlement and bearing resistance requirements at all applicable limit states, the distribution of bearing stress on the effective area shall be assumed to be:

- uniform for footings on soils, or
- linearly varying, i.e., triangular or trapezoidal as applicable, for footings on rock.

The distribution of bearing stress shall be determined as specified in Article 11.6.3.2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Bearing stress distributions for structural design of the footing shall be as specified in Article 10.6.5.

#### 10.6.1.5—Anchorage of Inclined Footings

Footings that are founded on inclined smooth solid rock surfaces and that are not restrained by an overburden of resistant material shall be effectively anchored by means of rock anchors, rock bolts, dowels, keys or other suitable means. Shallow keying of large footings shall be avoided where blasting is required for rock removal.

#### C10.6.1.5

Design of anchorages should include consideration of corrosion potential and protection.

#### 10.6.1.6—Groundwater

Spread footings shall be designed in consideration of the highest anticipated groundwater table.

The influences of groundwater table on the bearing resistance of soils or rock and on the settlement of the structure shall be considered. In cases where seepage forces are present, they should also be included in the analyses.

#### 10.6.1.7—Uplift

Where spread footings are subjected to uplift forces, they shall be investigated both for resistance to uplift and for structural strength.

#### 10.6.1.8—Nearby Structures

Where foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation and the effect of the foundation on the existing structures shall be investigated.

### 10.6.2—Service Limit State Design

#### 10.6.2.1—General

Service limit state design of spread footings shall include evaluation of total and differential settlement.

#### C10.6.2.1

The design of spread footings is frequently controlled by movement at the service limit state. It is therefore usually advantageous to proportion spread footings at the service limit state and check for adequate design at the strength and extreme limit states.

#### 10.6.2.2—Tolerable Movements

The requirements of Article 10.5.2.1 shall apply.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 10.6.2.3—Loads

Immediate settlement shall be determined using load combination Service I, as specified in Table 3.4.1-1. Time-dependent settlements in cohesive soils should be determined using only the permanent loads, i.e., transient loads should not be considered.

### C10.6.2.3

The type of load or the load characteristics may have a significant effect on spread footing deformation. The following factors should be considered in the estimation of footing deformation:

- The ratio of sustained load to total load;
- The duration of sustained loads; and
- The time interval over which settlement or lateral displacement occurs.

The consolidation settlements in cohesive soils are time-dependent; consequently, transient loads have negligible effect. However, in cohesionless soils where the permeability is sufficiently high, elastic deformation of the supporting soil due to transient load can take place. Because deformation in cohesionless soils often takes place during construction while the loads are being applied, it can be accommodated by the structure to an extent, depending on the type of structure and construction method.

Deformation in cohesionless, or granular, soils often occurs as soon as loads are applied. As a consequence, settlements due to transient loads may be significant in cohesionless soils, and they should be included in settlement analyses.

### 10.6.2.4—Settlement Analyses

#### *10.6.2.4.1—General*

Foundation settlements should be estimated using computational methods based on the results of laboratory or insitu testing, or both. The soil parameters used in the computations should be chosen to reflect the loading history of the ground, the construction sequence, and the effects of soil layering.

Both total and differential settlements, including time dependent effects, shall be considered.

Total settlement, including elastic, consolidation, and secondary components may be taken as:

$$S_t = S_e + S_c + S_s \qquad (10.6.2.4.1\text{-}1)$$

where:

$S_e$ = elastic settlement (ft)
$S_c$ = primary consolidation settlement (ft)
$S_s$ = secondary settlement (ft)

#### *C10.6.2.4.1*

Elastic, or immediate, settlement is the instantaneous deformation of the soil mass that occurs as the soil is loaded. The magnitude of elastic settlement is estimated as a function of the applied stress beneath a footing or embankment. Elastic settlement is usually small and neglected in design, but where settlement is critical, it is the most important deformation consideration in cohesionless soil deposits and for footings bearing on rock. For footings located on over-consolidated clays, the magnitude of elastic settlement is not necessarily small and should be checked.

In a nearly saturated or saturated cohesive soil, the pore water pressure initially carries the applied stress. As pore water is forced from the voids in the soil by the applied load, the load is transferred to the soil skeleton. Consolidation settlement is the gradual compression of the soil skeleton as the pore water is forced from the voids in the soil. Consolidation settlement is the most important deformation consideration in cohesive soil deposits that possess sufficient strength to safely support a spread footing. While consolidation settlement can occur in saturated cohesionless soils, the consolidation occurs quickly and is normally not distinguishable from the elastic settlement.

Secondary settlement, or creep, occurs as a result of the plastic deformation of the soil skeleton under a constant effective stress. Secondary settlement is of

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The effects of the zone of stress influence, or vertical stress distribution, beneath a footing shall be considered in estimating the settlement of the footing.

Spread footings bearing on a layered profile consisting of a combination of cohesive soil, cohesionless soil and/or rock shall be evaluated using an appropriate settlement estimation procedure for each layer within the zone of influence of induced stress beneath the footing.

Unless otherwise specified for a specific settlement estimation method, the distribution of vertical stress increase below circular or square and long rectangular footings, i.e., where $L > 5B$, may be estimated using Figure 10.6.2.4.1-1.

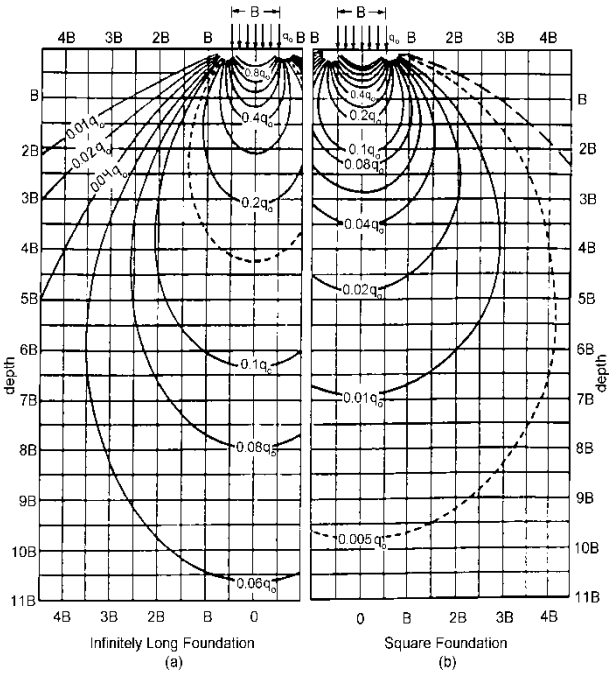

**Figure 10.6.2.4.1-1—Boussinesq Vertical Stress Contours for Continuous and Square Footings Modified after Sowers (1979)**

*10.6.2.4.2—Settlement of Footings on Cohesionless Soils*

*10.6.2.4.2a—General*

The settlement of spread footings bearing on cohesionless soil deposits shall be estimated as a function principal concern in highly plastic or organic soil deposits. Such deposits are normally so obviously weak and soft as to preclude consideration of bearing a spread footing on such materials.

The principal deformation component for footings on rock is elastic settlement, unless the rock or included discontinuities exhibit noticeable time-dependent behavior.

To avoid overestimation, relevant settlements should be evaluated using the construction-point concept described in Samtani et al. (2010).

For guidance on vertical stress distribution for complex footing geometries, see Poulos and Davis (1974) or Lambe and Whitman (1969).

Some methods used for estimating settlement of footings on sand include an integral method to account for the effects of vertical stress increase variations. For guidance regarding application of these procedures, see Gifford et al. (1987) and Samtani and Nowatzki (2006).

*C10.6.2.4.2a*

For general guidance regarding the estimation of elastic settlement of footings on cohesionless soils, see

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

of effective footing width and shall consider the effects of footing geometry and soil and rock layering with depth.

Settlements of footings on cohesionless soils shall be estimated using elastic theory or calibrated empirical procedures.

Gifford et al. (1987), and Kimmerling (2002), and Samtani and Nowatzki (2006).

Although methods are recommended for the determination of settlement of cohesionless soils, experience has indicated that settlements can vary considerably in a construction site, and this variation may not be predicted by conventional calculations.

Settlements of cohesionless soils occur rapidly, essentially as soon as the foundation is loaded. Therefore, the total settlement under the service loads may not be as important as the incremental settlement between intermediate load stages. For example, the total and differential settlement- due to loads applied by columns and cross beams is generally less important than the total and differential settlements due to girder placement and casting of continuous concrete decks.

The stress distributions used to calculate elastic settlement assume the footing is flexible and supported on a homogeneous soil of infinite depth. The settlement below a flexible footing varies from a maximum near the center to a minimum at the edge equal to about 50 percent and 64 percent of the maximum for rectangular and circular footings, respectively. The settlement profile for rigid footings is assumed to be uniform across the width of the footing.

Spread footings of the dimensions normally used for bridges are generally assumed to be rigid, although the actual performance will be somewhere between perfectly rigid and perfectly flexible, even for relatively thick concrete footings, due to stress redistribution and concrete creep.

Generally conservative settlement estimates may be obtained using the empirical methods by Hough and Schmertmann. Additional information regarding the accuracy of the methods described herein is provided in Gifford et al. (1987) and Kimmerling (2002), Samtani and Nowatzki (2006), and Samtani and Allen (2018). This information, in combination with local experience and engineering judgment, should be used when determining the estimated settlement for a structure foundation, as there may be cases, such as attempting to build a structure grade high to account for the estimated settlement, when overestimating the settlement magnitude could be problematic. Samtani and Allen (2018) found that soil settlement estimation using these methods does not provide meaningful results for estimated settlements of less than 0.5 in. Therefore, assessment of the angular distortions and associated force effects such as shear and moment in a structure resulting from differential settlement within or between foundation elements should not depend on the ability to predict a foundation settlement of less than 0.5 in. Hence, in cases where the estimated total settlement of footings on soil is less than 0.5 in., a minimum differential settlement of 0.5 in. should be assumed for calculating the angular distortions and associated force effects for structural analysis.

If the structure foundation is located in or adjacent to a bridge approach fill or reinforced soil structure,

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

settlement due the fill or reinforced soil structure should be included in the footing settlement estimate, unless the approach fill or reinforced soil structure settlement is allowed to occur before the bridge foundation is constructed. Both the Hough and Schmertmann methods have been successfully used to estimate fill/reinforced soil structure settlement when cohesionless soils are present (Samtani and Allen, 2018).

Details of other settlement estimation procedures can be found in textbooks and engineering manuals, including:

- Terzaghi and Peck (1967)
- Sowers (1979)
- U.S. Department of the Navy (1982)
- D'Appolonia (Gifford et al., 1987)—This method includes consideration for over-consolidated sands.
- Tomlinson (1986)
- Gifford et al. (1987)
- Elastic Half Space Method (Munkfakh et al., 2001)

These methods, however, have not been calibrated.

Calibration of local methods should be based on processes as described in Samtani and Kulicki (2018) and Samtani and Allen (2018).

Use of methods based on local geologic conditions and calibration require approval from the Owner.

*10.6.2.4.2b—Hough Method*

Estimation of spread footing settlement on cohesionless soils by the empirical Hough method shall be determined using Eqs. 10.6.2.4.2b-1 and 10.6.2.4.2b-2. *SPT* blow counts shall be corrected as specified in Article 10.4.6.2.4 for depth, i.e. overburden stress, and *SPT* hammer efficiency, before correlating the SPT blow counts to the bearing capacity index, $C'$.

$$S_e = \sum_{i=1}^{n} \Delta H_i \tag{10.6.2.4.2b-1}$$

in which:

$$\Delta H_i = H_c \frac{1}{C'} \log\left(\frac{\sigma'_o + \Delta\sigma_v}{\sigma'_o}\right) \tag{10.6.2.4.2b-2}$$

where:

$n$ = number of soil layers within zone of stress influence of the footing
$\Delta H_i$ = elastic settlement of layer $i$ (ft)
$H_c$ = initial height of layer $i$ (ft)
$C'$ = bearing capacity index from Figure 10.6.2.4.2b-1 (dim)
$\sigma'_o$ = initial vertical effective stress at the midpoint of layer $i$ (ksf)
$\Delta\sigma_v$ = increase in vertical stress at the midpoint of layer $i$ (ksf)

*C10.6.2.4.2b*

The Hough method was developed for normally consolidated cohesionless soils.

The Hough method has several advantages over other methods used to estimate settlement in cohesionless soil deposits, including express consideration of soil layering and the zone of stress influence beneath a footing of finite size.

The subsurface soil profile should be subdivided into layers based on stratigraphy to a depth of about three times the footing width. The maximum layer thickness should be about 10.0 ft.

While Hough (1959) did not specifically state that the *SPT N* values should be corrected for hammer energy in addition to overburden pressure, due to the vintage of the original work, hammers that typically have an efficiency of approximately 60 percent were in general used to develop the empirical correlations contained in the method. If using *SPT* hammers with efficiencies that differ significantly from this 60 percent value, the *N* values should also be corrected for hammer energy, in effect requiring that $N1_{60}$ be used (Samtani and Nowatzki, 2006).

Studies conducted by Gifford et al. (1987) and Samtani and Nowatzki (2006) indicate that Hough's procedure may be more conservative, but with less prediction variability, than the Schmertmann Method. However, this difference is mostly taken into account through the load factor, $\gamma_{SE}$, since it has been calibrated using reliability theory (Kulicki et al. 2015) (Samtani and Kulicki, 2018) (Samtani and Allen (2018).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

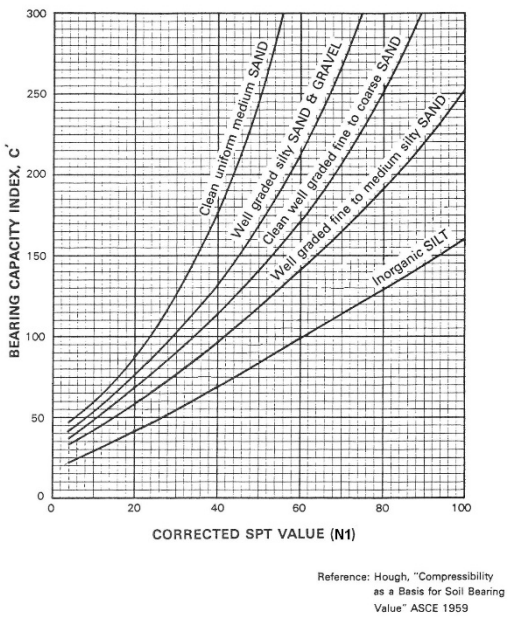

**Figure 10.6.2.4.2b-1—Bearing Capacity Index versus Corrected *SPT* (Hough, 1959, as modified in Samtani and Nowatzki, 2006)**

The Hough method is applicable to cohesionless soil deposits. The "Inorganic Silt" curve should generally not be applied to soils that exhibit plasticity because N-values in such soils are unreliable (Samtani and Nowatzki, 2006). The settlement characteristics of cohesive soils that exhibit plasticity should be investigated using undisturbed samples and laboratory consolidation tests as prescribed in Article 10.6.2.4.3.

*10.6.2.4.2c—Schmertmann Method*

Estimation of spread footing immediate, or elastic, settlement, $S_i$, on cohesionless soils by the empirical Schmertmann, method shall be calculated using Eq. 10.6.2.4.2c-1.

$$S_i = C_1 C_2 \Delta p \sum_{i=1}^{n} \Delta J_i \qquad (10.6.2.4.2c\text{-}1)$$

in which:

$$\Delta J_i = H_c \left( \frac{I_z}{144 XE} \right) \qquad (10.6.2.4.2c\text{-}2)$$

$$C_1 = 1 - 0.5 \left( \frac{p_o}{\Delta p} \right) \geq 0.5 \qquad (10.6.2.4.2c\text{-}3)$$

$$C_2 = 1 + 0.2 \log_{10} \left( \frac{t}{0.1} \right) \qquad (10.6.2.4.2c\text{-}4)$$

where:

$\Delta J_i$ = elastic spring stiffness of layer, $i$ (ft/ksf)
$H_c$ = height of compressible soil layer, $i$ (ft)
$I_z$ = strain influence factor from Figure 10.6.2.4.2c-1a. The dimensions $L_f$ and $B_f$ represent the least lateral dimension of the footing after correction for eccentricities, i.e., use effective footing dimension. The strain influence factor is a function of depth and is obtained from the strain influence diagram. The

*C10.6.2.4.2c*

Background information for this method, originally published in Schmertmann (1970) and Schmertmann et al. (1978), in the format as presented here can be found in Samtani and Nowatzki (2006). This method was originally developed for use with the static cone bearing resistance $q_c$, in which $q_c$ was correlated to the soil modulus, $E$, and $E$ is used directly in this method. The original formulation for this correlation by Schmertmann (1970) assumed $E$ was in units of tsf (i.e., $E$ (in tsf) = $2q_c$ (in tsf or kg/cm$^2$). The correlation in Table 10.6.2.4.2c-1 predicts $E$ in ksi. Correlations between $E$ and the *SPT N* values are also available and provided in Table 10.6.2.4.2c-1.

The variables in the equation for $\Delta J_i$ (Eq. 10.6.2.4.2c-2) require specific units for $H_c$ (ft) and $E$ (provided in Table 10.6.2.4.2c-1) is in ksi. This results in the units for $\Delta J_i$ being ft/ksf. Furthermore, in Eqs. 10.6.2.4.2c-1 and 10.6.2.4.2c-3, units of $p_o$ and $\Delta p$ must be ksf.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

strain influence diagram is constructed for the axisymmetric case ($L_f/B_f$ = 1) and the plane strain case ($L_f/B_f \geq 10$) as shown in Figure 10.6.2.4.2c-1a. The strain influence diagram for intermediate conditions should be determined by simple linear interpolation.

$n$ = number of soil layers within the zone of strain influence (strain influence diagram).

$\Delta p$ = net uniform applied stress (load intensity) at the foundation depth as shown in Figure 10.6.2.4.2c-1b in which $p$ is equal to the uniform applied footing stress, $\sigma_v$, as specified in Article 11.6.3.2 (see Figure 10.6.2.4.2c-1b) (ksf).

$E$ = elastic modulus of layer $i$, estimated using Table 10.6.2.4.2c-1 (ksi).

$X$ = a factor used to determine the value of elastic modulus. The value of elastic modulus is based on correlations with $N1_{60}$-values or $q_c$ from Table 10.6.2.4.2c-1, then values of $X$ shall be taken as follows:

$X$ = 1.25 for axisymmetric case ($L_f/B_f$ = 1)
$X$ = 1.75 for plane strain case ($L_f/B_f \geq 10$)

Use interpolation for footings with values of $L_f/B_f$ between 1 and 10. If the value of elastic modulus is based on in-situ testing (e.g., pressuremeter), use $X$ = 1.0.

$C_1$ = correction factor to incorporate the effect of strain relief due to embedment

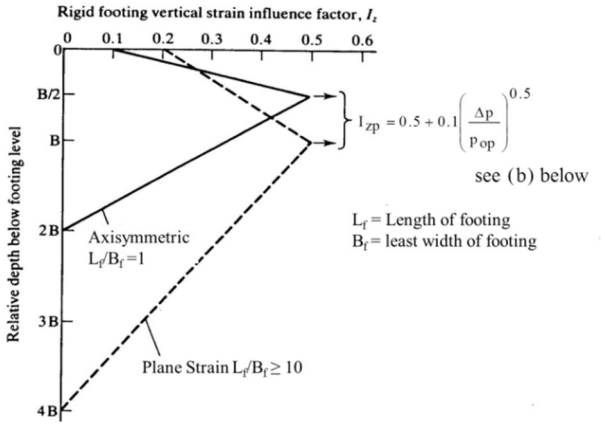
$p_o$ = effective in-situ overburden stress at the foundation depth as shown in Figure 10.6.2.4.2c-1b (ksf)

$p_{op}$ = effective in-situ overburden stress at the depth to peak strain influence factor, $I_{zp}$, as shown in Figure 10.6.2.4.2c-1b (ksf)

$\Delta p$ = net uniform applied stress (load intensity) at the foundation depth as shown in Figure 10.6.2.4.2c-1b in which p is equal to the uniform applied footing stress, $\sigma_v$, as specified in Article 11.6.3.2 (ksf).

$C_2$ = correction factor to incorporate time-dependent (creep) increase in settlement for time, $t$, after construction

$t$ = time from completion of construction to date under consideration for evaluation of $C_2$ (yrs)



The $C_2$ parameter shall not be used to estimate time-dependent consolidation settlements. Where consolidation settlement can occur within the depth of the strain distribution diagram, the magnitude of the consolidation settlement shall be estimated as per Article 10.6.2.4.3 and added to the immediate settlement of other layers within the strain distribution diagram where consolidation settlement may not occur.

For $C_2$, correction factor, the time duration, $t$, in Eq. 10.6.2.4.2c-4 is set to 0.1 years to evaluate the settlement immediately after construction, i.e., $C_2$ = 1. If long-term creep movement of the soil is suspected then an appropriate time duration, $t$, should be used in the computation of $C_2$. Creep movement is not the same as consolidation settlement. This factor can have an important influence on the reported settlement since it is included in Eq. 10.6.2.4.2c-1 as a multiplier. For example, the $C_2$ factor for time durations of 0.1 yrs, 1 yr, 10 yrs, and 50 yrs are 1.0, 1.2, 1.4, and 1.54, respectively. In cohesionless soils and unsaturated fine-grained cohesive soils with low plasticity, time durations of 0.1 yr and 1 yr, respectively, are generally appropriate and sufficient for cases of static loads.

*10.6.2.4.3—Settlement of Footings on Cohesive Soils*

Spread footings in which cohesive soils are located within the zone of stress influence shall be investigated for consolidation settlement. Elastic and secondary settlement shall also be investigated in consideration of the timing and sequence of construction loading and the tolerance of the structure to total and differential movements.

Where laboratory test results are expressed in terms of void ratio, $e$, the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where $\sigma'_p > \sigma'_o$, as illustrated in Figure 10.6.2.4.3-2:

$$S_c = \left[\frac{H_c}{1+e_o}\right]\left[C_r \log\left(\frac{\sigma'_p}{\sigma'_o}\right) + C_c \log\left(\frac{\sigma'_f}{\sigma'_p}\right)\right] \quad (10.6.2.4.3\text{-}1)$$

- For normally consolidated soils where $\sigma'_p = \sigma'_o$:

$$S_c = \left[\frac{H_c}{1+e_o}\right]\left[\left(C_c \log\frac{\sigma'_f}{\sigma'_p}\right)\right] \quad (10.6.2.4.3\text{-}2)$$

- For underconsolidated soils where $\sigma'_p < \sigma'_o$:

$$S_c = \left[\frac{H_c}{1+e_o}\right]\left[C_c \log\left(\frac{\sigma'_f}{\sigma'_{pc}}\right)\right] \quad (10.6.2.4.3\text{-}3)$$

Where laboratory test results are expressed in terms of vertical strain, $\varepsilon_v$, the consolidation settlement of footings shall be taken as:

- For overconsolidated soils where $\sigma'_p > \sigma'_o$, as illustrated in Figure 10.6.2.4.3-2:

$$S_c = H_c\left[C_{r\varepsilon} \log\left(\frac{\sigma'_p}{\sigma'_o}\right) + C_{c\varepsilon} \log\left(\frac{\sigma'_f}{\sigma'_p}\right)\right] \quad (10.6.2.4.3\text{-}4)$$

- For normally consolidated soils where $\sigma'_p = \sigma'_o$:

$$S_c = H_c C_{c\varepsilon} \log\left(\frac{\sigma'_f}{\sigma'_p}\right) \quad (10.6.2.4.3\text{-}5)$$

- For underconsolidated soils where $\sigma'_p < \sigma'_o$:

$$S_c = H_c C_{c\varepsilon} \log\left(\frac{\sigma'_f}{\sigma'_{pc}}\right) \quad (10.6.2.4.3\text{-}6)$$

*C10.6.2.4.3*

In practice, footings on cohesive soils are most likely founded on overconsolidated clays, and settlements can be estimated using elastic theory (Baguelin et al., 1978), or the tangent modulus method (Janbu, 1963, 1967). Settlements of footings on overconsolidated clay usually occur at approximately one order of magnitude faster than soils without preconsolidation, and it is reasonable to assume that they take place as rapidly as the loads are applied. Infrequently, a layer of cohesive soil may exhibit a preconsolidation stress less than the calculated existing overburden stress. The soil is then said to be underconsolidated because a state of equilibrium has not yet been reached under the applied overburden stress. Such a condition may have been caused by a recent lowering of the groundwater table. In this case, consolidation settlement will occur due to the additional load of the structure and the settlement that is occurring to reach a state of equilibrium. The total consolidation settlement due to these two components can be estimated by Eq. 10.6.2.4.3-3 or Eq. 10.6.2.4.3-6.

Normally consolidated and underconsolidated soils should be considered unsuitable for direct support of spread footings due to the magnitude of potential settlement, the time required for settlement, for low shear strength concerns, or any combination of these design considerations. Preloading or vertical drains may be considered to mitigate these concerns.

To account for the decreasing stress with increased depth below a footing and variations in soil compressibility with depth, the compressible layer should be divided into vertical increments, i.e., typically 5.0 to 10.0 ft for most normal width footings for highway applications, and the consolidation settlement of each increment analyzed separately. The total value of $S_c$ is the summation of $S_c$ for each increment.

The magnitude of consolidation settlement depends on the consolidation properties of the soil. These properties include the compression and recompression constants, $C_c$ and $C_r$, or $C_{c\varepsilon}$, and $C_{r\varepsilon}$; the preconsolidation stress, $\sigma'_p$; the current, initial vertical effective stress, $\sigma'_o$; and the final vertical effective stress after application of additional loading, $\sigma'_f$. An overconsolidated soil has been subjected to larger stresses in the past than at present. This could be a result of preloading by previously overlying strata, desiccation, groundwater lowering, glacial overriding or an engineered preload. If $\sigma'_o = \sigma'_p$, the soil is normally consolidated. Because the recompression constant is typically about an order of magnitude smaller than the compression constant, an accurate determination of the preconsolidation stress, $\sigma'_p$, is needed to make reliable estimates of consolidation settlement.

The reliability of consolidation settlement estimates is also affected by the quality of the consolidation test sample and by the accuracy with which changes in $\sigma'_p$ with depth are known or estimated. As shown in Figure C10.6.2.4.3-1, the slope of the e or $\varepsilon_v$ versus log

where:

$H_c$ = initial height of compressible soil layer (ft)
$e_o$ = void ratio at initial vertical effective stress (dim)
$C_r$ = recompression index (dim)
$C_c$ = compression index (dim)
$C_{r\varepsilon}$ = recompression ratio (dim)
$C_{c\varepsilon}$ = compression ratio (dim)
$\sigma'_p$ = maximum past vertical effective stress in soil at midpoint of soil layer under consideration (ksf)
$\sigma'_o$ = initial vertical effective stress in soil at midpoint of soil layer under consideration (ksf)

$\sigma'_f$ = final vertical effective stress in soil at midpoint of soil layer under consideration (ksf)
$\sigma'_{pc}$ = current vertical effective stress in soil, not including the additional stress due to the footing loads, at midpoint of soil layer under consideration (ksf)

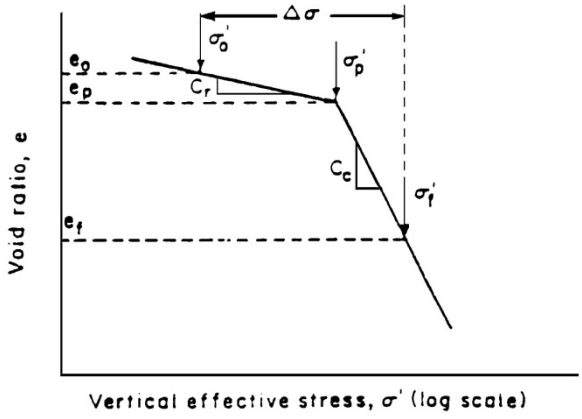

**Figure 10.6.2.4.3-1—Typical Consolidation Compression Curve for Overconsolidated Soil: Void Ratio versus Vertical Effective Stress, EPRI (1983)**

$\sigma'_v$ curve and the location of $\sigma'_p$ can be strongly affected by the quality of samples used for the laboratory consolidation tests. In general, the use of poor quality samples will result in an overestimate of consolidation settlement. Typically, the value of $\sigma'_p$ will vary with depth as shown in Figure C10.6.2.4.3-2. If the variation of $\sigma'_p$ with depth is unknown, e.g., only one consolidation test was conducted in the soil profile, actual settlements could be higher or lower than the computed value based on a single value of $\sigma'_p$.

The cone penetrometer test may be used to improve understanding of both soil layering and variation of $\sigma'_p$ with depth by correlation to laboratory tests from discrete locations.

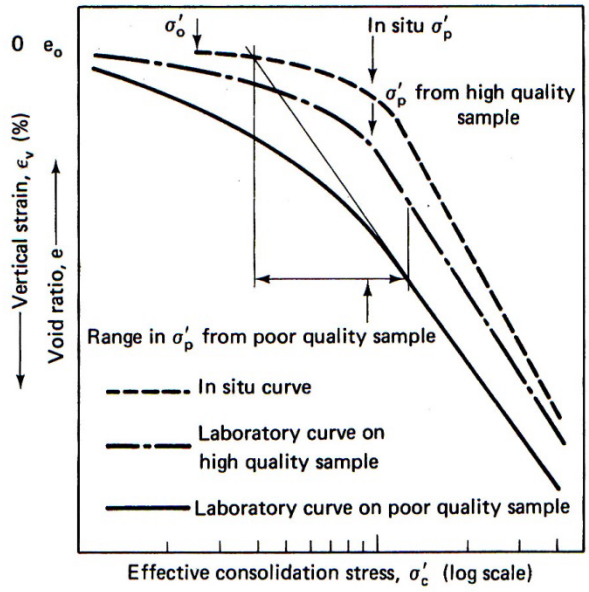

**Figure C10.6.2.4.3-1—Effects of Sample Quality on Consolidation Test Results, Holtz and Kovacs (1981)**

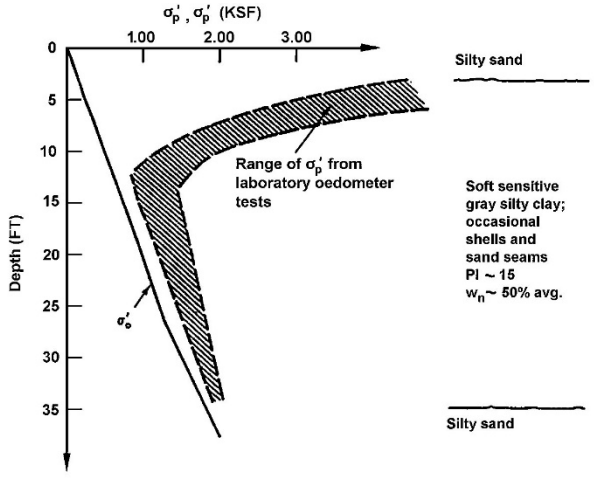

**Figure C10.6.2.4.3-2—Typical Variation of Preconsolidation Stress with Depth, Holtz and Kovacs (1981)**

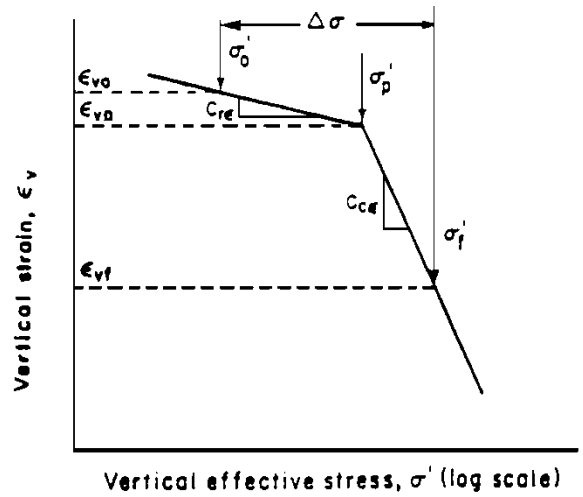

**Figure 10.6.2.4.3-2—Typical Consolidation Compression Curve for Overconsolidated Soil: Vertical Strain versus Vertical Effective Stress, EPRI (1983)**

If the footing width, $B$, is small relative to the thickness of the compressible soil, $H_c$, the effect of three-dimensional loading shall be considered and shall be taken as:

$$S_{c(3-D)} = \mu_c S_{c(1-D)} \qquad (10.6.2.4.3\text{-}7)$$

where:

$\mu_c$ = reduction factor taken as specified in Figure 10.6.2.4.3-3 (dim)
$S_{c(1\text{-}D)}$ = single dimensional consolidation settlement (ft)

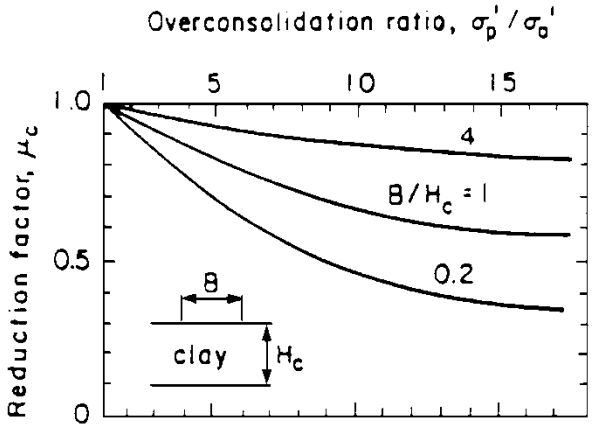

**Figure 10.6.2.4.3-3—Reduction Factor to Account for Effects of Three-dimensional Consolidation Settlement (EPRI, 1983)**

The time, $t$, to achieve a given percentage of the total estimated one-dimensional consolidation settlement shall be taken as:

Consolidation occurs when a saturated compressible layer of soil is loaded and water is squeezed out of the layer. The time required for the (primary) consolidation process to end will depend on the permeability of the soil. Because the time factor, $T$, is defined as logarithmic, the consolidation process theoretically never ends. The

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$t = \frac{TH_d^2}{c_v} \qquad (10.6.2.4.3\text{-}8)$$

where:

$T$ = time factor taken as specified in Figure 10.6.2.4.3-4 for the excess pore pressure distributions shown in the Figure (dim)
$H_d$ = length of longest drainage path in compressible layer under consideration (ft)
$c_v$ = coefficient of consolidation (ft²/yr)

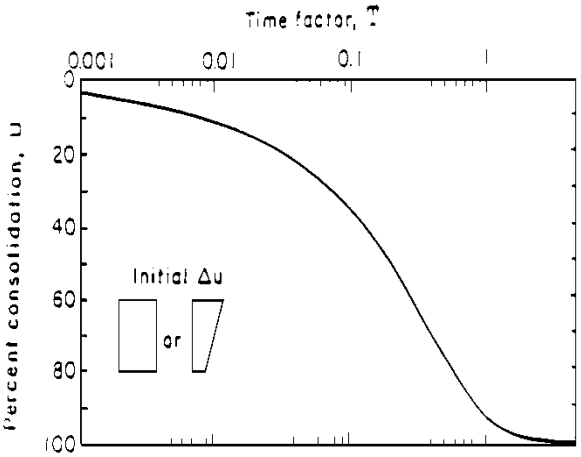

**Figure 10.6.2.4.3-4 Percentage of Consolidation as a Function of Time Factor, *T* (EPRI, 1983)**

Where laboratory test results are expressed in terms of void ratio, e, the secondary settlement of footings on cohesive soil shall be taken as:

$$S_s = \frac{C_\alpha}{1+e_o} H_c \log\left(\frac{t_2}{t_1}\right) \qquad (10.6.2.4.3\text{-}9)$$

Where laboratory test results are expressed in terms of vertical strain, $\varepsilon_v$, the secondary settlement of footings on cohesive soils shall be taken as:

$$S_s = C_{\alpha\varepsilon} H_c \log\left(\frac{t_2}{t_1}\right) \qquad (10.6.2.4.3\text{-}10)$$

practical assumption is usually made that the additional consolidation past 90 percent or 95 percent consolidation is negligible, or is taken into consideration as part of the total long-term settlement. Refer to Winterkorn and Fang (1975) for values of $T$ for excess pore pressure distributions other than indicated in Figure 10.6.2.4.3-4.

The length of the drainage path is the longest distance from any point in a compressible layer to a drainage boundary at the top or bottom of the compressible soil unit. Where a compressible layer is located between two drainage boundaries, $H_d$ equals one-half the actual height of the layer. Where a compressible layer is adjacent to an impermeable boundary (usually below), $H_d$ equals the full height of the layer.

Computations to predict the time rate of consolidation based on the result of laboratory tests generally tend to over-estimate the actual time required for consolidation in the field. This over-estimation is principally due to:

- the presence of thin drainage layers within the compressible layer that are not observed from the subsurface exploration nor considered in the settlement computations,
- the effects of three-dimensional dissipation of pore water pressures in the field, rather than the one-dimensional dissipation that is imposed by laboratory odometer tests and assumed in the computations, and
- the effects of sample disturbance, which tend to reduce the permeability of the laboratory tested samples.

If the total consolidation settlement is within the serviceability limits for the structure, the time rate of consolidation is usually of lesser concern for spread footings. If the total consolidation settlement exceeds the serviceability limitations, superstructure damage will occur unless provisions are made for timing of closure pours as a function of settlement, simple support of spans and/or periodic jacking of bearing supports.

Secondary compression component if settlement results from compression of bonds between individual clay particles and domains, as well as other effects on the microscale that are not yet clearly understood (Holtz and Kovacs, 1981). Secondary settlement is most important for highly plastic clays and organic and micaceous soils. Accordingly, secondary settlement predictions should be considered as approximate estimates only.

If secondary compression is estimated to exceed serviceability limitations, either deep foundations or ground improvement should be considered to mitigate the effects of secondary compression. Experience indicates preloading and surcharging may not be effective in eliminating secondary compression.

where:

$H_c$ = initial height of compressible soil layer (ft)
$e_o$ = void ratio at initial vertical effective stress (dim)
$t_1$ = time when secondary settlement begins, i.e., typically at a time equivalent to 90 percent average degree of primary consolidation (yr)
$t_2$ = arbitrary time that could represent the service life of the structure (yr)
$C_\alpha$ = secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)
$C_{\alpha\varepsilon}$ = modified secondary compression index estimated from the results of laboratory consolidation testing of undisturbed soil samples (dim)

*10.6.2.4.4—Settlement of Footings on Rock*

For footings bearing on fair to very good rock, according to the Geomechanics Classification system and designed in accordance with the provisions of this Section, elastic settlements may generally be assumed to be less than 0.5 in. When elastic settlements of this magnitude are unacceptable or when the rock is not competent, an analysis of settlement based on rock mass characteristics shall be made.

Where rock is broken or jointed (relative rating of ten or less for *RQD* and joint spacing), the rock joint condition is poor (relative rating of ten or less) or the criteria for fair to very good rock are not met, a settlement analysis should be conducted, and the influence of rock type, condition of discontinuities, and degree of weathering shall be considered in the settlement analysis.

The elastic settlement of footings on broken or jointed rock, in feet, should be taken as:

- For circular (or square) footings:

$$\rho = q_o\left(1-\nu^2\right)\frac{rI_p}{144\,E_m} \qquad (10.6.2.4.4\text{-}1)$$

in which:

$$I_p = \frac{\left(\sqrt{\pi}\right)}{\beta_z} \qquad (10.6.2.4.4\text{-}2)$$

- For rectangular footings:

$$\rho = q_o\left(1-\nu^2\right)\frac{BI_p}{144\,E_m} \qquad (10.6.2.4.4\text{-}3)$$

in which:

$$I_p = \frac{\left(L/B\right)^{1/2}}{\beta_z} \qquad (10.6.2.4.4\text{-}4)$$

*C10.6.2.4.4*

In most cases, it is sufficient to determine settlement using the average bearing stress under the footing.

Where the foundations are subjected to a very large load or where settlement tolerance may be small, settlements of footings on rock may be estimated using elastic theory. The stiffness of the rock mass should be used in such analyses.

The accuracy with which settlements can be estimated by using elastic theory is dependent on the accuracy of the estimated rock mass modulus, $E_m$. In some cases, the value of $E_m$ can be estimated through empirical correlation with the value of the modulus of elasticity for the intact rock between joints. For unusual or poor rock mass conditions, it may be necessary to determine the modulus from in-situ tests, such as plate loading and pressuremeter tests.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

where:

$q_o$ = applied vertical stress at base of loaded area (ksf)
$\nu$ = Poisson's Ratio (dim)
$r$ = radius of circular footing or $B/2$ for square footing (ft)
$I_p$ = influence coefficient to account for rigidity and dimensions of footing (dim)
$E_m$ = rock mass modulus (ksi)
$\beta_z$ = factor to account for footing shape and rigidity (dim)

Values of $I_p$ should be computed using the $\beta_z$ values presented in Table 10.6.2.4.4-1 for rigid footings. Where the results of laboratory testing are not available, values of Poisson's ratio, $\nu$, for typical rock types may be taken as specified in Table C10.4.6.5-2. Determination of the rock mass modulus, $E_m$, should be based on the methods described in Sabatini (2002).

The magnitude of consolidation and secondary settlements in rock masses containing soft seams or other material with time-dependent settlement characteristics should be estimated by applying procedures specified in Article 10.6.2.4.3.

**Table 10.6.2.4.4-1—Elastic Shape and Rigidity Factors, EPRI (1983)**

| *L*/*B* | Flexible, $\beta_z$ (average) | $\beta_z$ Rigid |

| Circular | 1.04 | 1.13 |
| 1 | 1.06 | 1.08 |
| 2 | 1.09 | 1.10 |
| 3 | 1.13 | 1.15 |
| 5 | 1.22 | 1.24 |
| 10 | 1.41 | 1.41 |

### 10.6.2.5—Bearing Resistance at the Service Limit State

*10.6.2.5.1—Presumptive Values for Bearing Resistance*

The use of presumptive values shall be based on knowledge of geological conditions at or near the structure site.

*C10.6.2.5.1*

Unless more appropriate regional data are available, the presumptive values given in Table C10.6.2.5.1-1 may be used. These bearing resistances are settlement limited, e.g., 1.0 in., and apply only at the service limit state.

*10.6.2.5.2—Semiempirical Procedures for Bearing Resistance*

Bearing resistance on rock shall be determined using empirical correlation to the Geomechanic Rock Mass Rating System, RMR. Local experience should be considered in the use of these semi-empirical procedures.

If the recommended value of presumptive bearing resistance exceeds either the unconfined compressive strength of the rock or the nominal resistance of the concrete, the presumptive bearing resistance shall be taken as the lesser of the unconfined compressive strength of the rock or the nominal resistance of the concrete. The nominal resistance of concrete shall be taken as $0.3f'_c$.

## 10.6.3—Strength Limit State Design

### 10.6.3.1—Bearing Resistance of Soil

*10.6.3.1.1—General*

Bearing resistance of spread footings shall be determined based on the highest anticipated position of groundwater level at the footing location.

The factored bearing resistance, $q_R$, at the strength limit state shall be taken as:

$$q_R = \varphi_b \, q_n \qquad (10.6.3.1.1\text{-}1)$$

where:

$\varphi_b$ = resistance factor specified in Article 10.5.5.2.2
$q_n$ = nominal bearing resistance (ksf)

Where loads are eccentric, the effective footing dimensions, $L'$ and $B'$, as specified in Article 10.6.1.3, shall be used instead of the overall dimensions $L$ and $B$ in all equations, tables, and figures pertaining to bearing resistance.

*C10.6.3.1.1*

The bearing resistance of footings on soil should be evaluated using soil shear strength parameters that are representative of the soil shear strength under the loading conditions being analyzed. The bearing resistance of footings supported on granular soils should be evaluated for both permanent dead loading conditions and short-duration live loading conditions using effective stress methods of analysis and drained soil shear strength parameters. The bearing resistance of footings supported on cohesive soils should be evaluated for short-duration live loading conditions using total stress methods of analysis and undrained soil shear strength parameters. In addition, the bearing resistance of footings supported on cohesive soils, which could soften and lose strength with time, should be evaluated for permanent dead loading conditions using effective stress methods of analysis and drained soil shear strength parameters.

The position of the groundwater table can significantly influence the bearing resistance of soils through its effect on shear strength and unit weight of the foundation soils. In general, the submergence of soils will reduce the effective shear strength of cohesionless (or granular) materials, as well as the long-term (or drained) shear strength of cohesive (clayey) soils. Moreover, the effective unit weights of submerged soils are about half of those for the same soils under dry conditions. Thus, submergence may lead to a significant reduction in the bearing resistance provided by the foundation soils, and it is essential that the bearing resistance analyses be carried out under the assumption of the highest groundwater table expected within the service life of the structure.

Footings with inclined bases should be avoided wherever possible. Where use of an inclined footing base cannot be avoided, the nominal bearing resistance determined in accordance with the provisions herein should be further reduced using accepted corrections for inclined footing bases in Munfakh et al. (2001).

Because the effective dimensions will vary slightly for each limit state under consideration, strict adherence to this provision will require re-computation of the nominal bearing resistance at each limit state.

Further, some of the equations for the bearing resistance modification factors based on $L$ and $B$ were not necessarily or specifically developed with the intention that effective dimensions be used. The designer should ensure that appropriate values of $L$ and $B$ are used, and that effective footing dimensions $L'$ and $B'$ are used appropriately.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Consideration should be given to the relative change in the computed nominal resistance based on effective versus gross footing dimensions for the size of footings typically used for bridges. Judgment should be used in deciding whether the use of gross footing dimensions for computing nominal bearing resistance at the strength limit state would result in a conservative design.

*10.6.3.1.2—Theoretical Estimation*

*10.6.3.1.2a—Basic Formulation*

*C10.6.3.1.2a*

The nominal bearing resistance shall be estimated using accepted soil mechanics theories and should be based on measured soil parameters. The soil parameters used in the analyses shall be representative of the soil shear strength under the considered loading and subsurface conditions.

The nominal bearing resistance of spread footings on cohesionless soils shall be evaluated using effective stress analyses and drained soil strength parameters.

The nominal bearing resistance of spread footings on cohesive soils shall be evaluated for total stress analyses and undrained soil strength parameters. In cases where the cohesive soils may soften and lose strength with time, the bearing resistance of these soils shall also be evaluated for permanent loading conditions using effective stress analyses and drained soil strength parameters.

For spread footings bearing on compacted soils, the nominal bearing resistance shall be evaluated using the more critical of either total or effective stress analyses.

Except as noted below, the nominal bearing resistance of a soil layer, in ksf, should be taken as:

$$q_n = cN_{cm} + \gamma_q D_f N_{qm} C_{wq} + 0.5\gamma_f B N_{\gamma m} C_{w\gamma} \quad (10.6.3.1.2a\text{-}1)$$

The bearing resistance formulation provided in Eqs. 10.6.3.1.2a-1 though 10.6.3.1.2a-4 is the complete formulation as described in the Munfakh et al. (2001). However, in practice, not all of the factors included in these equations have been routinely used.

in which:

$$N_{cm} = N_c s_c i_c \quad (10.6.3.1.2a\text{-}2)$$

$$N_{qm} = N_q s_q d_q i_q \quad (10.6.3.1.2a\text{-}3)$$

$$N_\gamma m = N_\gamma s_\gamma i_\gamma \quad (10.6.3.1.2a\text{-}4)$$

where:

$c$ = cohesion, taken as undrained shear strength (ksf)

$N_c$ = cohesion term (undrained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)

$N_q$ = surcharge (embedment) term (drained or undrained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)

$N_\gamma$ = unit weight (footing width) term (drained loading) bearing capacity factor as specified in Table 10.6.3.1.2a-1 (dim)
$\gamma_q$ = total (moist) unit weight of soil above the bearing depth of the footing (kcf)
$\gamma_f$ = total (moist) unit weight of soil below the bearing depth of the footing (kcf)
$D_f$ = footing embedment depth (ft)
$B$ = footing width (ft)
$C_{wq}$,$C_{w\gamma}$ = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)
$s_c$, $s_\gamma$,$s_q$ = footing shape correction factors as specified in Table 10.6.3.1.2a-3 (dim)
$d_q$ = depth correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation determined from Eq. 10.6.3.1.2a-10 (dim)
$i_c$, $i_\gamma$, $i_q$ = load inclination factors determined from Eqs. 10.6.3.1.2a-5 or 10.6.3.1.2a-6, and 10.6.3.1.2a-7 and 10.6.3.1.2a-8 (dim)

For $\phi_f$ = 0:

$$i_c = 1 - (nH/cBLN_c) \qquad (10.6.3.1.2a\text{-}5)$$

For $\phi_f$ > 0:

$$i_c = i_q - [(1 - i_q)/(N_q - 1)] \qquad (10.6.3.1.2a\text{-}6)$$

in which:

$$i_q = \left[1 - \frac{H}{(V + cBL\cot\phi_f)}\right]^n \qquad (10.6.3.1.2a\text{-}7)$$

$$i_\gamma = \left[1 - \frac{H}{V + cBL\cot\phi_f)}\right]^{(n+1)} \qquad (10.6.3.1.2a\text{-}8)$$

$$n = [(2 + L/B)/(1 + L/B)]\cos^2\theta + [(2 + B/L)/(1 + B/L)]\sin^2\theta \qquad (10.6.3.1.2a\text{-}9)$$

where:

$B$ = footing width (ft)
$L$ = footing length (ft)
$H$ = unfactored horizontal load (kips)
$V$ = unfactored vertical load (kips)
$\theta$ = projected direction of load in the plane of the footing, measured from the side of length $L$ (degrees)

Most geotechnical engineers nationwide have not used the load inclination factors. This is due, in part, to the lack of knowledge of the vertical and horizontal loads at the time of geotechnical explorations and preparation of bearing resistance recommendations.

Furthermore, the basis of the load inclination factors computed by Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8 is a combination of bearing resistance theory and small scale load tests on 1.0 in. wide plates on London Clay and Ham River Sand (Meyerhof, 1953). Therefore, the factors do not take into consideration the effects of depth of embedment. Meyerhof further showed that for footings with a depth of embedment ratio of $D_f/B$ = 1, the effects of load inclination on bearing resistance are relatively small. The theoretical formulation of load inclination factors were further examined by Brinch-Hansen (*1970*), with additional modification by Vesic (*1973*) into the form provided in Eqs. 10.6.3.1.2a-5 to 10.6.3.1.2a-8.

It should further be noted that the resistance factors provided in Article 10.5.5.2.2 were derived for vertical loads. The applicability of these resistance factors to design of footings resisting inclined load combinations is not currently known. The combination of the resistance factors and the load inclination factors may be overly conservative for footings with an embedment of approximately $D_f/B$ = 1 or deeper because the load inclination factors were derived for footings without embedment.

In practice, therefore, for footings with modest embedment, consideration may be given to omission of the load inclination factors.

Figure C10.6.3.1.2a-1 shows the convention for determining the θ angle in Eq. 10.6.3.1.2a-9.

**Table 10.6.3.1.2a-3—Shape Correction Factors $s_c$, $s_\gamma$, $s_q$**

| Factor | Friction Angle | Cohesion Term ($s_c$) | Unit Weight Term ($s_\gamma$) | Surcharge Term ($s_q$) |
|---|---|---|---|---|
| Shape Factors $s_c$, $s_\gamma$, $s_q$ | $\phi_f = 0$ | $1+\left(\frac{B}{5L}\right)$ | 1.0 | 1.0 |
| | $\phi_f > 0$ | $1+\left(\frac{B}{L}\right)\left(\frac{N_q}{N_c}\right)$ | $1-0.4\left(\frac{B}{L}\right)$ | $1+\left(\frac{B}{L}\tan\phi_f\right)$ |

$$d_q = 1 + 2\tan\phi_f(1-\sin\phi_f)^2 \arctan\left(\frac{D_f}{B}\right) \quad (10.6.3.1.2a\text{-}10)$$

Eq. 10.6.3.1.2a-10 has been verified to cover a range of friction angle, $\phi_f$, of 32 degrees to 42 degrees, and a range of $D_f/B$ of 1 to 8. Depth correction factor values beyond this range have not been verified at this time.

where:

$d_q$ = depth correction factor to account for the shearing resistance along the failure surface passing through cohesionless material above the bearing elevation(dim)
$\phi_f$ = angle of internal friction of soil (degrees)
$D_f$ = footing embedment depth (ft)
$B$ = footing width (ft)

Arctan ($D_f/B$) is in radians.

The depth correction factor should be used only when the soils above the footing bearing elevation are as competent as the soils beneath the footing level; otherwise, the depth correction factor should be taken as 1.0. The depth correction factor, $d_q$, shall not exceed 1.4.

*10.6.3.1.2b—Considerations for Punching Shear*

*C10.6.3.1.2b*

If local or punching shear failure is possible, the nominal bearing resistance shall be estimated using reduced shear strength parameters $c^*$ and $\phi^*$ in Eqs. 10.6.3.1.2b-1 and 10.6.3.1.2b-2. The reduced shear parameters may be taken as:

$$c^* = 0.67c \quad (10.6.3.1.2b\text{-}1)$$

$$\phi^* = \tan^{-1}(0.67\tan\phi_f) \quad (10.6.3.1.2b\text{-}2)$$

where:

$c^*$ = reduced effective stress soil cohesion for punching shear (ksf)
$\phi^*$ = reduced effective stress soil friction angle for punching shear (degrees)

Local shear failure is characterized by a failure surface that is similar to that of a general shear failure but that does not extend to the ground surface, ending somewhere in the soil below the footing. Local shear failure is accompanied by vertical compression of soil below the footing and visible bulging of soil adjacent to the footing but not by sudden rotation or tilting of the footing. Local shear failure is a transitional condition between general and punching shear failure. Punching shear failure is characterized by vertical shear around the perimeter of the footing and is accompanied by a vertical movement of the footing and compression of the soil immediately below the footing but does not affect the soil outside the loaded area. Punching shear failure occurs in loose or compressible soils, in weak soils under slow (drained) loading, and in dense sands for deep footings subjected to high loads.

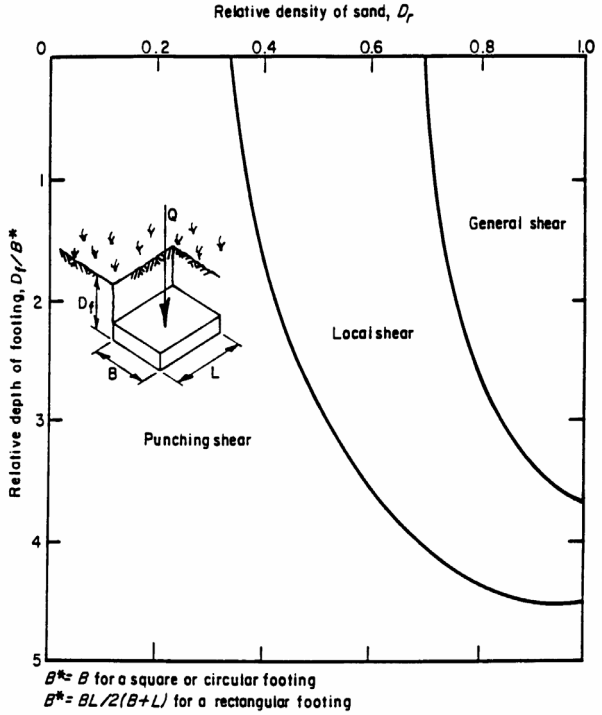

**Figure C10.6.3.1.2b-1—Modes of Bearing Capacity Failure for Footings in Sand**

*10.6.3.1.2c—Considerations for Footings on Slopes*

For footings constructed on or adjacent to slopes, the nominal bearing resistance shall be determined using a reduction coefficient ($RC_{BC}$) as presented in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2. The reduction coefficient should be applied directly to the nominal bearing resistance calculated from Eq.10.6.3.1.2a-1 for footings on level ground and supported on the same foundation soil conditions.

The nominal resistance of footings on or adjacent to slopes shall be taken as:

$$q_{n-sloping\ ground} = RC_{BC} q_n = RC_{BC}\left(cN_c + 0.5\gamma BN_\gamma\right) \quad (10.6.3.1.2c\text{-}1)$$

where:

$q_{n\text{-}sloping\ ground}$ = the nominal footing bearing resistance considering the effect of sloping ground (ksf)
$RC_{BC}$ = reduction coefficient for bearing resistance due to slope effects (dim)

and other variables are as defined in Article 10.6.3.1.2a and Figure 10.6.3.1.2c-1. The bearing capacity factors $N_c$ and $N_\gamma$ are obtained in accordance with Article 10.6.3.1.2a.

Reduction coefficients ($RC_{BC}$) should be determined using the definitions illustrated in Figure 10.6.3.1.2c-1

*C10.6.3.1.2c*

A rational approach for determining a modified bearing resistance for footings on or adjacent to a slope is presented in Leshchinsky (2015) and Leshchinsky and Xie (2016). These methods are considered valid and applicable to structure foundations in addition to the MSE retaining wall example presented in the reference papers. The reduction coefficients provided in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2 are modified and reconfigured by the author of the cited papers to allow for more convenient use in practice. See the original papers for the complete tabulation of reduction coefficient values.

The reduction coefficients are applicable to purely cohesive, purely cohesionless and $c$-$\phi$ soils. The $RC_{BC}$ factors are based on no footing embedment for footings either on or adjacent to slopes and may be conservative for deep footing embedment depths.

Limit analysis, or limit equilibrium analysis, should be considered to estimate the nominal bearing resistance of footings on or adjacent to slopes composed of soils and/or site conditions that are not consistent with the parameters and conditions described in the reference documents (i.e. embedment >0, layered soils, steeper slopes).

The schematic shown in Figure 10.6.3.1.2c-1 is provided only for illustrating and defining the terms used in the design equations and tables. This figure should not be used as the basis for locating footings on slopes regarding embedment depth and setback.

for footings on or adjacent to slopes. Use linear interpolation to obtain reduction coefficients for values not provided. The slope stability factor, $N_s$, in Tables 10.6.3.1.2c-1 and 10.6.3.1.2c-2 shall be taken as:

$$N_s = \frac{\gamma H_s}{c} \qquad (10.6.3.1.2c\text{-}2)$$

where:

$N_s$ = slope stability factor (dim)
$H_s$ = height of sloping ground surface below bottom of footing (ft)

and other variables are as defined in Article 10.6.3.1.2a.

*10.6.3.1.2d—Considerations for Two-Layer Soil Systems—Critical Depth*

Where the soil profile contains a second layer of soil with different properties affecting shear strength within a distance below the footing less than $H_{crit}$, the bearing resistance of the layered soil profile shall be determined using the provisions for two-layered soil systems herein. The distance $H_{crit}$, in feet, may be taken as:

$$H_{crit} = \frac{(3B)\ \ln\left(\frac{q_1}{q_2}\right)}{2\left(1+\frac{B}{L}\right)} \qquad (10.6.3.1.2d\text{-}1)$$

where:

$q_1$ = nominal bearing resistance of footing supported in the upper layer of a two-layer system, assuming the upper layer is infinitely thick (ksf)
$q_2$ = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)
$B$ = footing width (ft)
$L$ = footing length (ft)

*10.6.3.1.2e—Two-Layered Soil System in Undrained Loading*

Where a footing is supported on a two-layered soil system subjected to undrained loading, the nominal bearing resistance may be determined using Eq. 10.6.3.1.2a-1 with the following modifications:

$c_1$ = undrained shear strength of the top layer of soil as depicted in Figure 10.6.3.1.2e-1 (ksf)
$N_{cm}$ = $N_m$, a bearing capacity factor as specified below (dim)
$N_{qm}$ = 1.0 (dim)

Where the bearing stratum overlies a stiffer cohesive soil, $N_m$, may be taken as specified in Figure 10.6.3.1.2e-2.

Where the bearing stratum overlies a softer cohesive soil, $N_m$ may be taken as:

$$N_m = \left(\frac{1}{\beta_m} + \kappa s_c N_c\right) \le s_c N_c \qquad (10.6.3.1.2e\text{-}1)$$

in which:

$$\beta_m = \frac{BL}{2(B+L)H_{s2}} \qquad (10.6.3.1.2e\text{-}2)$$

*C10.6.3.1.2e*

Vesic' (1970) developed a rigorous solution for the modified bearing capacity factor, $N_m$, for the weak undrained layer over strong undrained layer situation. This solution is given by the following equation:

$$N_m = \frac{\kappa N_c^*(N_c^* + \beta_m - 1)A}{B\ \ C - (\kappa N_c^* + \beta_m - 1))(N_c^* + 1)} \qquad (C10.6.3.1.2e\text{-}1)$$

in which:

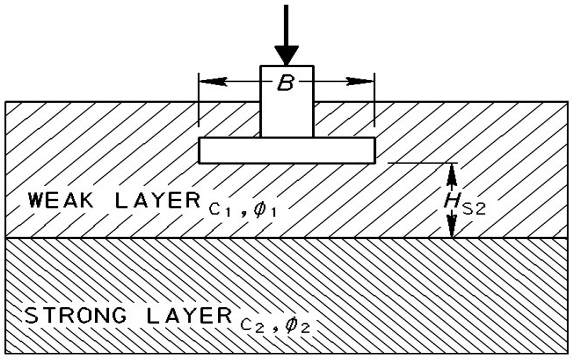
$$A = \left[(\kappa+1)N_c^{*2} + (1+\kappa\beta_m)N_c^* + \beta_m - 1\right. \qquad (C10.6.3.1.2e\text{-}2)$$

$$B = \left[\kappa(\kappa+1)N_c^* + \kappa + \beta_m - 1\right] \qquad (C10.6.3.1.2e\text{-}3)$$

$$C = \left[(N_c^* + \beta_m)N_c^* + \beta_m - 1\right] \qquad (C10.6.3.1.2e\text{-}4)$$

- For circular or square footings:

$$\beta_m = \frac{B}{4H_{s2}} \qquad (C10.6.3.1.2e\text{-}5)$$



$$N_c^* = 6.17$$

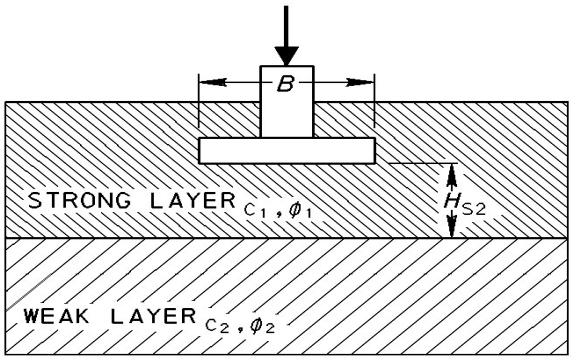
All rights reserved. Duplication is a violation of applicable law.



$$\kappa = \frac{c_2}{c_1} \qquad (10.6.3.1.2e\text{-}3)$$

where:

$\beta_m$ = punching index (dim)
$c_1$ = undrained shear strength of upper soil layer (ksf)
$c_2$ = undrained shear strength of lower soil layer (ksf)
$H_{s2}$ = distance from bottom of footing to top of the second soil layer (ft)
$s_c$ = shape correction factor determined from Table 10.6.3.1.2a-3
$N_c$ = bearing capacity factor determined herein (dim)
$N_{qm}$ = bearing capacity factor determined herein (dim)

( a )

( b )

**Figure 10.6.3.1.2e-1—Two-Layer Soil Profiles**

- For strip footings:

$$\beta_m = \frac{B}{2H_{s2}} \qquad (C10.6.3.1.2e\text{-}6)$$

$$N_c^* = 5.14$$

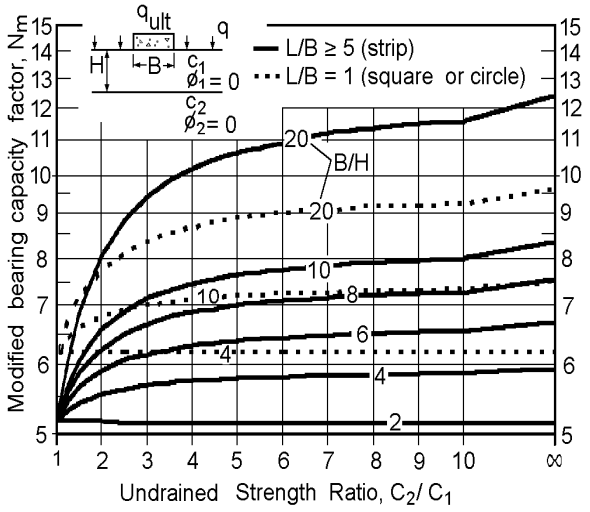

**Figure 10.6.3.1.2e-2—Modified Bearing Factor for Two-Layer Cohesive Soil with Weaker Soil Overlying Stronger Soil (EPRI, 1983)**

*10.6.3.1.2f—Two-Layered Soil System in Drained Loading*

*C10.6.3.1.2f*

Where a footing supported on a two-layered soil system is subjected to a drained loading, the nominal bearing resistance, in ksf, may be taken as:

$$q_n = \left[ q_2 + \left(\frac{1}{K}\right) c'_1 \cot \phi'_1 \right] e^{2\left[1+\left(\frac{B}{L}\right)\right] K \tan \phi'_1 \left(\frac{H_{s2}}{B}\right)} - \left(\frac{1}{K}\right) c'_1 \cot \phi'_1 \quad (10.6.3.1.2f\text{-}1)$$

in which:

$$K = \frac{1-\sin^2 \phi'_1}{1+\sin^2 \phi'_1} \quad (10.6.3.1.2f\text{-}2)$$

where:

$c'_1$ = drained shear strength of the top layer of soil in a two-layer system, such as depicted in Figure 10.6.3.1.2e-1 (ksf)

$q_2$ = nominal bearing resistance of a fictitious footing of the same size and shape as the actual footing but supported on surface of the second (lower) layer of a two-layer system (ksf)

$\phi'_1$ = effective stress angle of internal friction of the top layer of soil (degrees)

If the upper layer is a cohesionless soil and $\phi'$ equals 25–50 degrees, Eq. 10.6.3.1.2f-1 reduces to:

$$q_n = q_2 e^{0.67\left[1+\left(\frac{B}{L}\right)\right]\frac{H_{s2}}{B}} \quad (C10.6.3.1.2f\text{-}1)$$

*10.6.3.1.3—Semiempirical Procedures*

*C10.6.3.1.3*

The nominal bearing resistance of foundation soils may be estimated from the results of in-situ tests or by observed resistance of similar soils. The use of a particular in-situ test and the interpretation of test results should take local experience into consideration. The following in-situ tests may be used:

In application of these empirical methods, the use of average *SPT* blow counts and *CPT* tip resistances is specified. The resistance factors recommended for bearing resistance included in Table 10.5.5.2.2-1 assume the use of average values for these parameters. The use of lower bound values may result in an overly conservative design. However, depending on the availability of soil

© 2020 by the American Association of State Highway and Transportation Officials.

- Standard Penetration Test (*SPT*)
- Cone Penetration Test (*CPT*)

The nominal bearing resistance in sand, in ksf, based on *SPT* results may be taken as:

$$q_n = \frac{\bar{N}1_{60} B}{5}\left(C_{wq}\frac{D_f}{B} + C_{w\gamma}\right) \qquad (10.6.3.1.3\text{-}1)$$

where:

$\bar{N}1_{60}$ = average *SPT* blow count corrected for both overburden and hammer efficiency effects (blows/ft) as specified in Article 10.4.6.2.4. Average the blow count over a depth range from the bottom of the footing to 1.5*B* below the bottom of the footing.
$B$ = footing width (ft)
$C_{wq}$, $C_{w\gamma}$ = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)
$D_f$ = footing embedment depth taken to the bottom of the footing (ft)

The nominal bearing resistance, in ksf, for footings on cohesionless soils based on *CPT* results may be taken as:

$$q_n = \frac{\overline{q_c} B}{40}\left(C_{wq}\frac{D_f}{B} + C_{w\gamma}\right) \qquad (10.6.3.1.3\text{-}2)$$

where:

$\overline{q_c}$ = average cone tip resistance within a depth range, *B*, below the bottom of the footing (ksf)
$B$ = footing width (ft)
$C_{wq}$, $C_{w\gamma}$ = correction factors to account for the location of the groundwater table as specified in Table 10.6.3.1.2a-2 (dim)
$D_f$ = footing embedment depth taken to the bottom of the footing (ft)

*10.6.3.1.4—Plate Load Tests*

The nominal bearing resistance may be determined by plate load tests, provided that adequate subsurface explorations have been made to determine the soil profile below the foundation. Where plate load tests are conducted, they should be conducted in accordance with ASTM D1194.

The nominal bearing resistance determined from a plate load test may be extrapolated to adjacent footings where the subsurface profile is confirmed by subsurface exploration to be similar.

property data and the variability of the geologic strata under consideration, it may not be possible to reliably estimate the average value of the properties needed for design. In such cases, the Engineer may have no choice but to use a more conservative selection of design input parameters to mitigate the additional risks created by potential variability or the paucity of relevant data.

The original derivation of Eqs. 10.6.3.1.3-1 and 10.6.3.1.3-2 did not include inclination factors (Meyerhof, 1956).

*C10.6.3.1.4*

Plate load tests have a limited depth of influence and furthermore may not disclose the potential for long-term consolidation of foundation soils.

Scale effects should be addressed when extrapolating the results to performance of full scale footings. Extrapolation of the plate load test data to a full scale footing should be based on the design procedures provided herein for settlement (service limit state) and bearing resistance (strength and extreme event limit state), with consideration to the effect of the stratification, e.g., layer thicknesses, depths, and properties. Plate load test results should be applied only within a sub-area of the

project site for which the subsurface conditions, e.g., stratification, geologic history, and properties, are relatively uniform.

### 10.6.3.2—Bearing Resistance of Rock

*10.6.3.2.1—General*

*C10.6.3.2.1*

The methods used for design of footings on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site.

For footings on competent rock, reliance on simple and direct analyses based on uniaxial compressive rock strengths and *RQD* may be applicable. For footings on less competent rock, more detailed investigations and analyses shall be performed to account for the effects of weathering and the presence and condition of discontinuities.

The designer shall judge the competency of a rock mass by taking into consideration both the nature of the intact rock and the orientation and condition of discontinuities of the overall rock mass. Where engineering judgment does not verify the presence of competent rock, the competency of the rock mass should be verified using the procedures for RMR rating.

The design of spread footings bearing on rock is frequently controlled by either overall stability, e.g., the orientation and conditions of discontinuities, or load eccentricity considerations. The designer should verify adequate overall stability and size the footing based on eccentricity requirements at the strength limit state before checking nominal bearing resistance at both the service and strength limit states.

The design procedures for foundations in rock have been developed using the RMR, rock mass rating system. Classification of the rock mass should be according to the RMR system. For additional information on the RMR system, see Sabatini et al. (2002).

*10.6.3.2.2—Semiempirical Procedures*

*C10.6.3.2.2*

The nominal bearing resistance of rock should be determined using empirical correlation with the Geomechanics RMR system. Local experience shall be considered in the use of these semi-empirical procedures.

The factored bearing stress of the foundation shall not be taken to be greater than the factored compressive resistance of the footing concrete.

The bearing resistance of jointed or broken rock may be estimated using the semi-empirical procedure developed by Carter and Kulhawy (1988). This procedure is based on the unconfined compressive strength of the intact rock core sample. Depending on rock mass quality measured in terms of RMR system, the nominal bearing resistance of a rock mass varies from a small fraction to six times the unconfined compressive strength of intact rock core samples.

*10.6.3.2.3—Analytic Method*

*C10.6.3.2.3*

The nominal bearing resistance of foundations on rock shall be determined using established rock mechanics principles based on the rock mass strength parameters. The influence of discontinuities on the failure mode shall also be considered.

Depending upon the relative spacing of joints and rock layering, bearing capacity failures for foundations on rock may take several forms. Except for the case of a rock mass with closed joints, the failure modes are different from those in soil. Procedures for estimating bearing resistance for each of the failure modes can be found in Kulhawy and Goodman (1987), Goodman (1989), and Sowers (1979).

*10.6.3.2.4—Load Test*

Where appropriate, load tests may be performed to determine the nominal bearing resistance of foundations on rock.

### 10.6.3.3—Eccentric Load Limitations

**C10.6.3.3**

The eccentricity of loading at the strength limit state, evaluated based on factored loads shall not exceed:

A comprehensive parametric study was conducted for cantilevered retaining walls of various heights and soil

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- One-third of the corresponding footing dimension, $B$ or $L$, for footings on soils, or 0.45 of the corresponding footing dimensions $B$ or $L$, for footings on rock.

conditions. The base widths obtained using the LRFD load factors and eccentricity of $B/3$ were comparable to those of ASD with an eccentricity of $B/6$. For foundations on rock, to obtain equivalence with ASD specifications, a maximum eccentricity of $B/2$ would be needed for LRFD. However, a slightly smaller maximum eccentricity has been specified to account for the potential unknown future loading that could push the resultant outside the footing dimensions.

### 10.6.3.4—Failure by Sliding

### C10.6.3.4

Failure by sliding shall be investigated for footings that support horizontal or inclined load and/or are founded on slopes.

For foundations on clay soils, the possible presence of a shrinkage gap between the soil and the foundation shall be considered. If passive resistance is included as part of the shear resistance required for resisting sliding, consideration shall also be given to possible future removal of the soil in front of the foundation.

The factored resistance against failure by sliding, in kips, shall be taken as:

$$R_R = \varphi R_n = \varphi_\tau R_\tau + \varphi_{ep} R_{ep} \qquad (10.6.3.4\text{-}1)$$

where:

$\varphi$ = resistance factor (dim)
$R_n$ = nominal sliding resistance against failure by sliding (kips)
$\varphi_\tau$ = resistance factor for shear resistance between soil and foundation specified in Table 10.5.5.2.2-1
$R_\tau$ = nominal sliding resistance between soil and foundation (kips)
$\varphi_{ep}$ = resistance factor for passive resistance specified in Table 10.5.5.2.2-1
$R_{ep}$ = nominal passive resistance of soil available throughout the design life of the structure (kips)

Sliding failure occurs if the force effects due to the horizontal component of loads exceed the more critical of either the factored shear resistance of the soils or the factored shear resistance at the interface between the soil and the foundation.

For footings on cohesionless soils, sliding resistance depends on the roughness of the interface between the foundation and the soil.

The magnitudes of active earth load and passive resistance depend on the type of backfill material, the wall movement, and the compactive effort. Their magnitude can be estimated using procedures described in Sections 3 and 11.

In most cases, the movement of the structure and its foundation will be small. Consequently, if passive resistance is included in the resistance, its magnitude is commonly taken as 50 percent of the maximum passive resistance. This is the basis for the resistance factor, $\varphi_{ep}$, in Table 10.5.5.2.2-1.

The units for $R_R$, $R_n$, and $R_{ep}$ are shown in kips. For elements designed on a unit length basis, these quantities will have the units of kips per unit length.

If the soil beneath the footing is cohesionless, the nominal sliding resistance between soil and foundation shall be taken as:

$$R_\tau = CV \tan \phi_f \qquad (10.6.3.4\text{-}2)$$

for which:

$C$ = 1.0 for concrete cast against soil
= 0.8 for precast concrete footing

where:

$\phi_f$ = internal friction angle of drained soil (degrees)
$V$ = total vertical force (kips)

Sliding resistance between the base of a shallow foundation and a granular soil is governed by the coefficient of friction (tan δ) between the foundation soil and the footing. The value of the coefficient of friction is a function of the soil type and the roughness of the footing. For concrete cast against cohesionless or granular material, the footing base is rough, and the coefficient of friction, tan δ, will be equal to the tangent of the friction angle (tan $\phi_f$) for the soil supporting the footing. If the bottom of the footing consists of something other than concrete cast against the ground, then the coefficient of friction (tan δ) is not solely a property of the soil but is also a function of the footing material type and the roughness of the footing material. For the case of a precast concrete footing, assuming the concrete is smooth, the coefficient of friction should be set equal to 80 percent of tan $\phi_f$. See Article C3.11.5.3 for additional guidance and

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For footings that rest on clay, where footings are supported on at least 6.0 in. of compacted granular material,the sliding resistance may be taken as the lesser of:

- the cohesion of the clay, or
- one-half the normal stress on the interface between the footing and soil, as shown in Figure 10.6.3.4-1 for retaining walls.

The following notation shall be taken to apply to Figure 10.6.3.4-1:

$q_s$ = unit shear resistance, equal to $S_u$ or 0.5 $\sigma'_v$, whichever is less (ksf)
$R_\tau$ = nominal sliding resistance between soil and foundation (kips) expressed as the shaded area under the $q_s$ diagram
$S_u$ = undrained shear strength (ksf)
$\sigma'_v$ = vertical effective stress (ksf)

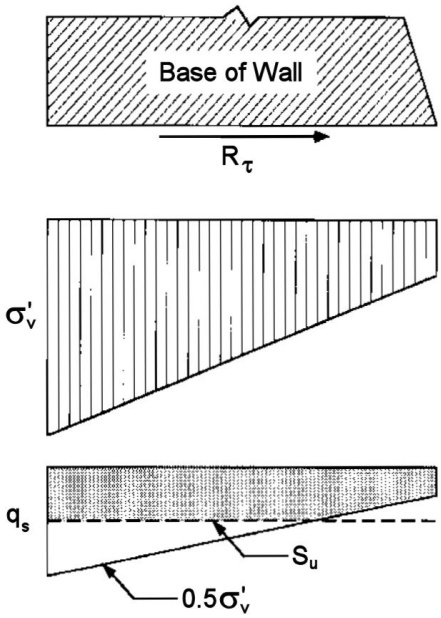

**Figure 10.6.3.4-1—Procedure for Estimating Nominal Sliding Resistance for Walls on Clay**

### 10.6.3.5—Overall Stability

Overall stability of a footing shall be evaluated where one or more of the following conditions exist:

background on the determination of interface friction values.

In the absence of specific data (e.g., measured $\phi_f$ from laboratory testing, $\phi_f$ determined through correlation to in-situ measured *SPT* or cone resistance values, or measured tan δ from laboratory testing), experience has shown that Table C3.11.5.3-1 may be used to estimate the coefficient of friction tan δ between soil and various footing material types in Eq. 10.6.3.4-2.

All rights reserved. Duplication is a violation of applicable law.

- Horizontal or inclined loads are present,
- The foundation is placed on embankment,
- The footing is located on, near or within a slope,
- The possibility of loss of foundation support through erosion or scour exists, or
- Bearing strata are significantly inclined.

### 10.6.4—Extreme Event Limit State Design

#### 10.6.4.1—General

Extreme limit state design checks for spread footings shall include, but not necessarily be limited to:

- bearing resistance,
- eccentric load limitations (overturning),
- sliding, and
- overall stability.

Resistance factors shall be as specified in Article 10.5.5.3.

#### 10.6.4.2—Eccentric Load Limitations

For footings, whether on soil or on rock, the eccentricity of loading for extreme limit states shall not exceed the limits provided in Article 11.6.5.

If live loads act to reduce the eccentricity for the Extreme I limit state, $\gamma_{EQ}$ shall be taken as 0.0.

### 10.6.5—Structural Design

The structural design of footings shall comply with the requirements given in Section 5.

For structural design of an eccentrically loaded foundation, a triangular or trapezoidal contact stress distribution based on factored loads shall be used for footings bearing on all soil and rock conditions.

**C10.6.5**

For purposes of structural design, it is usually assumed that the bearing stress varies linearly across the bottom of the footing. This assumption results in the slightly conservative triangular or trapezoidal contact stress distribution.

## 10.7—DRIVEN PILES

### 10.7.1—General

#### 10.7.1.1—Application

Driven piling should be considered in the following situations:

- When spread footings cannot be founded on rock, or on competent soils at a reasonable cost;
- At locations where soil conditions would normally permit the use of spread footings but the potential exists for scour, liquefaction or lateral spreading, in which case driven piles bearing on suitable materials below susceptible soils should be considered for use as a protection against these problems;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Where right-of-way or other space limitations would not allow the use spread footings;
- Where existing soil, contaminated by hazardous materials, must be removed for the construction of spread footings; or
- Where an unacceptable amount of settlement of spread footings may occur.

### 10.7.1.2—Minimum Pile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 2.5 pile diameters. The distance from the side of any pile to the nearest edge of the pile cap shall not be less than 9.0 in.

The tops of piles shall project at least 12.0 in. into the pile cap after all damaged material has been removed. If the pile is attached to the cap by embedded bars or strands, the pile shall extend no less than 6.0 in. into the cap.

Where a reinforced concrete beam is cast-in-place and used as a bent cap supported by piles, the concrete cover on the sides of the piles shall not be less than 6.0 in., plus an allowance for permissible pile misalignment. Where pile reinforcement is anchored in the cap satisfying the requirements of Article 5.12.9.1, the projection may be less than 6.0 in.

### 10.7.1.3—Piles through Embankment Fill

Piles to be driven through embankments should penetrate a minimum of 10.0 ft through original ground unless refusal on bedrock or competent bearing strata occurs at a lesser penetration.

Fill used for embankment construction should be a select material, which does not obstruct pile penetration to the required depth.

### C10.7.1.3

If refusal occurs at a depth of less than 10 ft, other foundation types, e.g., footings or shafts, may be more effective.

To minimize the potential for obstruction of the piles, the maximum size of any rock particles in the fill should not exceed 6.0 in. Pre-drilling or spudding pile locations should be considered in situations where obstructions in the embankment fill cannot be avoided, particularly for displacement piles. Note that predrilling or spudding may reduce the pile side resistance and lateral resistance, depending on how the predrilling or spudding is conducted. The diameter of the predrilled or spudded hole, and the potential for caving of the hole before the pile is installed will need to be considered to assess the effect this will have on side and lateral resistance.

If compressible soils are located beneath the embankment, piles should be driven after embankment settlement is complete, if possible, to minimize or eliminate downdrag forces.

### 10.7.1.4—Batter Piles

When the lateral resistance of the soil surrounding the piles is inadequate to counteract the horizontal forces transmitted to the foundation, or when increased rigidity of the entire structure is required, batter piles should be considered for use. Where negative side resistance (downdrag) loads are expected, batter piles should be avoided. If batter piles are used in areas of significant

### C10.7.1.4

In some cases, it may be desirable to use batter piles. From a general viewpoint, batter piles provide a much stiffer resistance to lateral loads than would be possible with vertical piles. They can be very effective in resisting static lateral loads.

Due to increased foundation stiffness, batter piles may not be desirable in resisting lateral dynamic loads if

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

seismic loading, the design of the pile foundation shall recognize the increased foundation stiffness that results.

### 10.7.1.5—Pile Design Requirements

Pile design shall address the following issues as appropriate:

- Nominal bearing resistance to be specified in the contract, type of pile, and size of pile group required to provide adequate support, with consideration of how nominal bearing pile resistance will be determined in the field.
- Group interaction.
- Pile quantity estimation and estimated pile penetration required to meet nominal axial resistance and other design requirements.
- Minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads, and seismic conditions.
- Foundation deflection to meet the established movement and associated structure performance criteria.
- Pile foundation nominal structural resistance.
- Pile drivability to confirm that acceptable driving stresses and blow counts can be achieved at the nominal bearing resistance, and at the estimated resistance to reach the minimum tip elevation, if a minimum tip elevation is required, with an available driving system.
- Long-term durability of the pile in service, i.e., corrosion and deterioration.

### 10.7.1.6—Determination of Pile Loads

*10.7.1.6.1—General*

The loads and load factors to be used in pile foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual pile loads are described in Section 4.

*10.7.1.6.2—Downdrag*

The provisions of Article 3.11.8 shall apply for determination of load due to negative side resistance.

Where piles are driven to end bearing on a dense stratum or rock and the design of the pile is structurally controlled, downdrag shall be considered at the strength and extreme limit states.

the structure is located in an area where seismic loads are potentially high.

**C10.7.1.5**

The driven pile design process is discussed in detail in Hannigan et al. (2006).

*C10.7.1.6.1*

The specification and determination of top of cap loads is discussed in Section 3. The Engineer should select different levels of analysis, detail and accuracy as appropriate for the structure under consideration. Details are discussed in Section 4.

*C10.7.1.6.2*

Downdrag occurs when settlement of soils along the side of the piles results in downward movement of the soil relative to the pile. See Article C3.11.8.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For friction piles that can experience settlement at the pile tip, downdrag shall be considered at the service, strength and extreme limit states. Estimate pile and pile group settlement according to Article 10.7.2.

In the case of friction piles with limited tip resistance, the downdrag load can exceed the geotechnical resistance of the pile, causing the pile to move downward enough to allow service limit state criteria for the structure to be exceeded. Where pile settlement is not limited by nominal bearing resistance below the downdrag zone, service limit state tolerances will govern the geotechnical design.

This design situation is not desirable and the preferred practice is to mitigate the downdrag induced foundation settlement through a properly designed surcharge and/or preloading program, or by extending the piles deeper for higher resistance.

The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive side and tip resistance below the lowest layer contributing to downdrag computed as specified in Article 3.11.8.

Instrumented static load tests, dynamic tests with signal matching, or static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available nominal resistance to withstand the downdrag plus structure loads.

*10.7.1.6.3—Uplift Due to Expansive Soils*

*C10.7.1.6.3*

Piles penetrating expansive soil shall extend to a depth into moisture-stable soils sufficient to provide adequate anchorage to resist uplift. Sufficient clearance should be provided between the ground surface and underside of caps or beams connecting piles to preclude the application of uplift loads at the pile/cap connection due to swelling ground conditions.

Evaluation of potential uplift loads on piles extending through expansive soils requires evaluation of the swell potential of the soil and the extent of the soil strata that may affect the pile. One reasonably reliable method for identifying swell potential is presented in Table 10.4.6.3-1. Alternatively, ASTM D4829 may be used to evaluate swell potential. The thickness of the potentially expansive stratum must be identified by:

- examination of soil samples from borings for the presence of jointing, slickensiding, or a blocky structure and for changes in color, and
- laboratory testing for determination of soil moisture content profiles.

*10.7.1.6.4—Nearby Structures*

*C10.7.1.6.4*

Where pile foundations are placed adjacent to existing structures, the influence of the existing structure on the behavior of the foundation, and the effect of the new foundation on the existing structures, including vibration effects due to pile installation, shall be investigated.

Vibration due to pile driving can cause settlement of existing foundations as well as structural damage to the adjacent facility, especially in loose cohesionless soils. The combination of taking measures to mitigate the vibration levels through use of nondisplacement piles, predrilling, proper hammer choice, etc., and a good vibration monitoring program should be considered.

## 10.7.2—Service Limit State Design

### 10.7.2.1—General

### C10.7.2.1

Service limit state design of driven pile foundations includes the evaluation of settlement due to static loads, and downdrag loads if present, lateral squeeze, and lateral deformation.

The deformation caused by unbalanced lateral forces such as due to overall stability or lateral squeeze should be evaluated and addressed in the design of the pile foundation.

Lateral analysis of pile foundations is conducted to establish the load distribution between the superstructure and foundations for all limit states, and to estimate the deformation in the foundation that will occur due to those loads. This Article only addresses the evaluation of the lateral deformation of the foundation resulting from the distributed loads.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 10.7.2.2—Tolerable Movements

The provisions of Article 10.5.2.1 shall apply.

### C10.7.2.2

See Article C10.5.2.1.

### 10.7.2.3—Settlement

#### *10.7.2.3.1—Equivalent Footing Analogy*

For purposes of calculating the settlements of pile groups, loads should be assumed to act on an equivalent footing based on the depth of embedment of the piles into the layer that provides support as shown in Figures 10.7.2.3.1-1 and 10.7.2.3.1-2.

Pile group settlement shall be evaluated for pile foundations in cohesive soils, soils that include cohesive layers, and piles in loose granular soils. The load used in calculating settlement shall be the permanently applied load on the foundation.

In applying the equivalent footing analogy for pile foundation, the reduction to equivalent dimensions $B'$ and $L'$ as used for spread footing design does not apply.

#### *C10.7.2.3.1*

Pile design should ensure that strength limit state considerations are satisfied before checking service limit state considerations.

For piles embedded adequately into dense granular soils such that the equivalent footing is located on or within the dense granular soil, and furthermore are not subjected to downdrag loads, a detailed assessment of the pile group settlement may be waived.

Methods for calculating settlement are discussed in Hannigan et al. (2006).

All rights reserved. Duplication is a violation of applicable law.

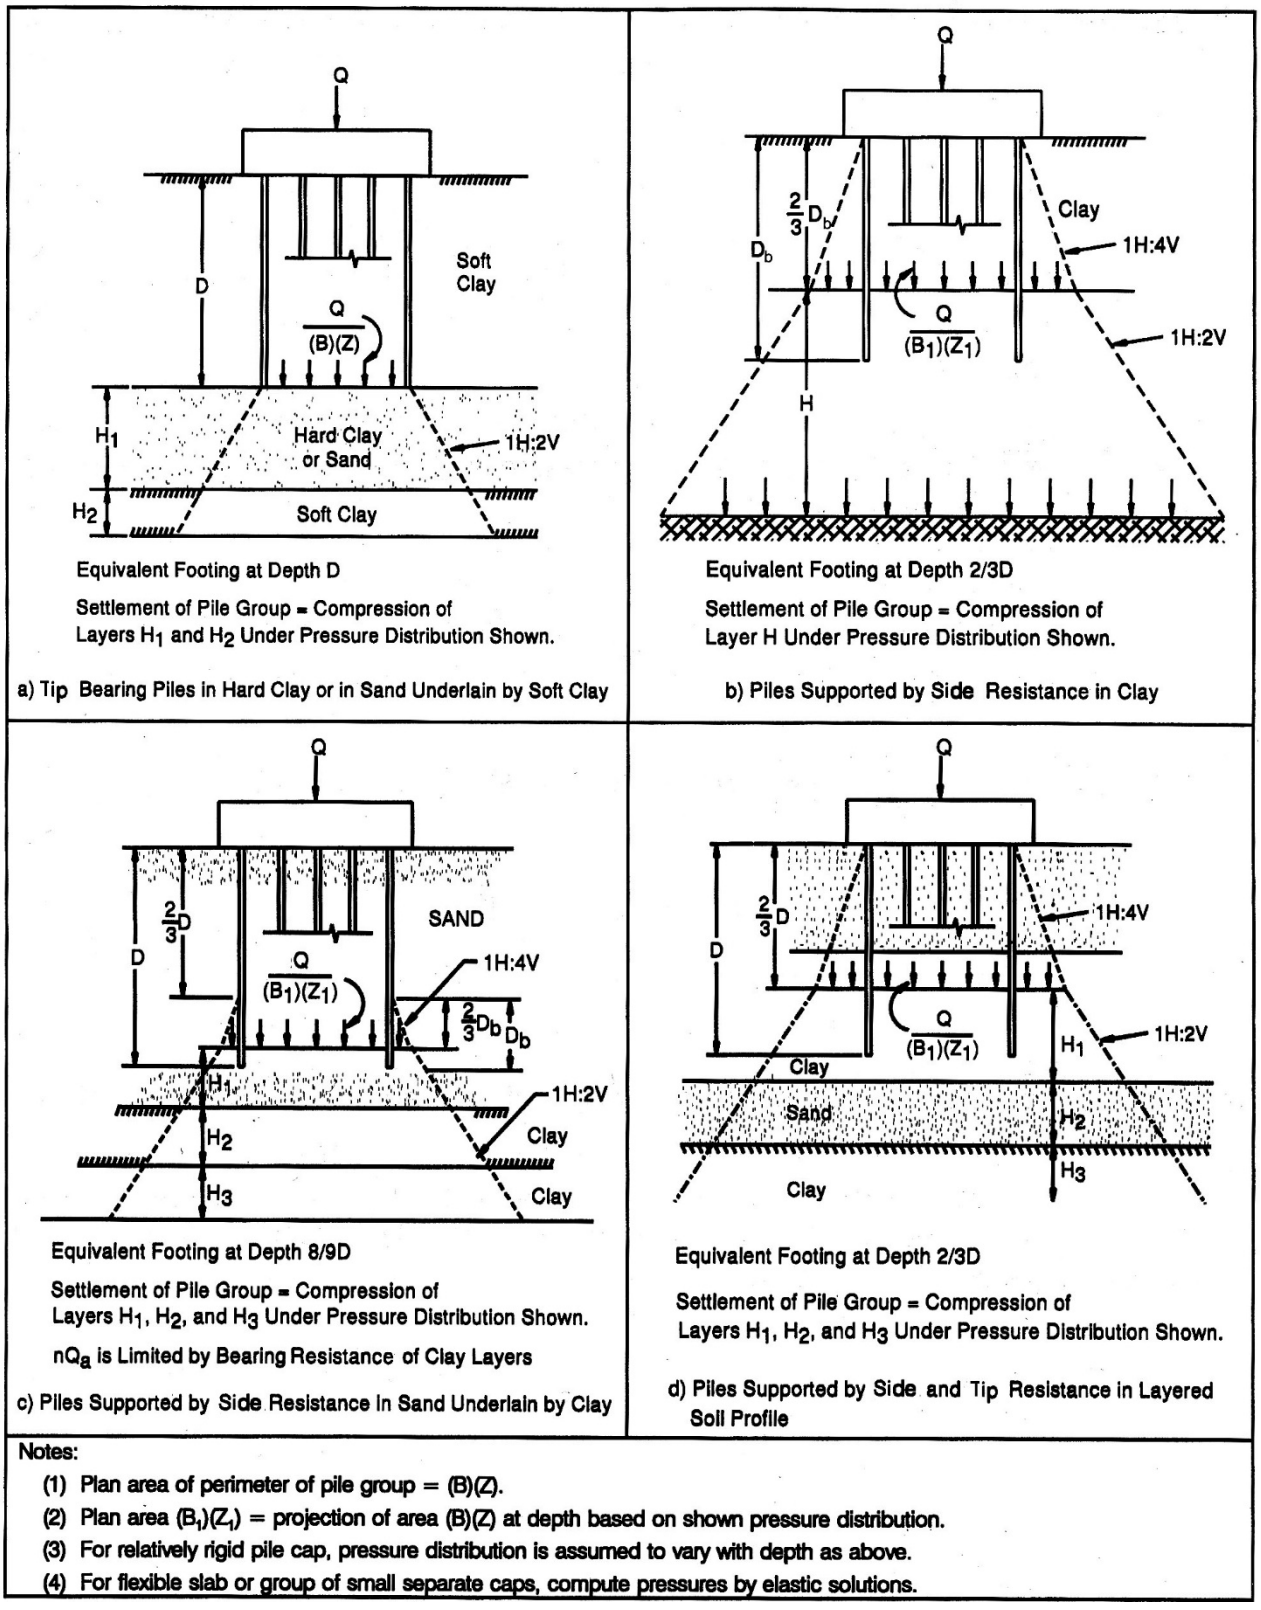

**Figure 10.7.2.3.1-1—Stress Distribution below Equivalent Footing for Pile Group after Hannigan et al. (2006)**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

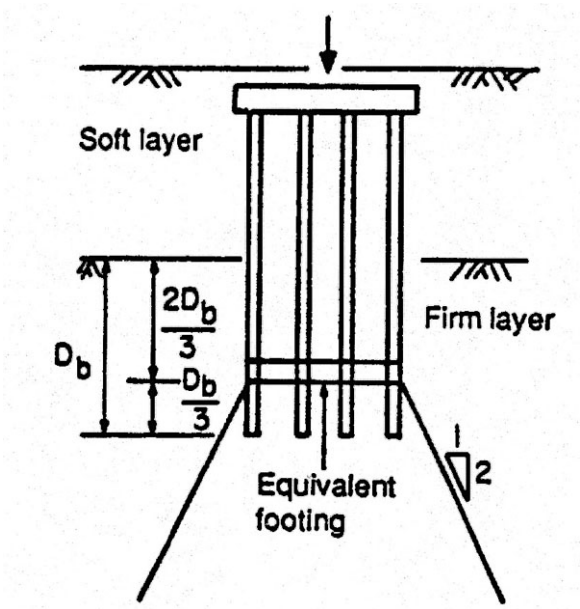

**Figure 10.7.2.3.1-2—Location of Equivalent Footing (after Duncan and Buchignani, 1976)**

*10.7.2.3.2—Pile Groups in Cohesive Soil*

Shallow foundation settlement estimation procedures shall be used to estimate the settlement of a pile group, using the equivalent footing location specified in Figure 10.7.2.3.1-1 or Figure 10.7.2.3.1-2.

The settlement of pile groups in cohesionless soils may be taken as:

Using *SPT*: $$\rho = \frac{qI\sqrt{B}}{N1_{60}} \qquad (10.7.2.3.2\text{-}1)$$

Using *CPT*: $$\rho = \frac{qBI}{2q_c} \qquad (10.7.2.3.2\text{-}2)$$

in which:

$$I = 1 - 0.125\frac{D'}{B} \geq 0.5 \qquad (10.7.2.3.2\text{-}3)$$

where:

$\rho$ = settlement of pile group (in.)
$q$ = net foundation pressure applied at $2D_b/3$, as shown in Figure 10.7.2.3.1-1; this pressure is equal to the applied load at the top of the group divided by the area of the equivalent footing and does not include the weight of the piles or the soil between the piles (ksf)
$B$ = width or smallest dimension of pile group (ft)

*C10.7.2.3.2*

The provisions are based upon the use of empirical correlations proposed by Meyerhof (1976). These are empirical correlations and the units of measure must match those specified for correct computations. This method may tend to over-predict settlements.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$I$ = influence factor of the effective group embedment (dim)
$D'$ = effective depth taken as $2D_b/3$ (ft)
$D_b$ = depth of penetration into bearing strata (ft)
$N1_{60}$ = *SPT* blow count corrected for both overburden and hammer efficiency effects (blows/ft) as specified in Article 10.4.6.2.4.
$q_c$ = static cone tip resistance (ksf)

Alternatively, other methods for computing settlement in cohesionless soil, such as the Hough method as specified in Article 10.6.2.4.2 may also be used in connection with the equivalent footing approach.

The corrected *SPT* blow count or the static cone tip resistance should be averaged over a depth equal to the pile group width $B$ below the equivalent footing. The *SPT* and *CPT* methods (Eqs. 10.7.2.3.2-1 and 10.7.2.3.2-2) shall only be considered applicable to the distributions shown in Figure 10.7.2.3.1-1b and Figure 10.7.2.3.1-2.

### 10.7.2.4—Horizontal Pile Foundation Movement

Horizontal movement induced by lateral loads shall be evaluated. The provisions of Article 10.5.2.1 shall apply regarding horizontal movement criteria.

The horizontal movement of pile foundations shall be estimated using procedures that consider soil-structure interaction. Tolerable horizontal movements of piles shall be established on the basis of confirming compatible movements of structural components, e.g., pile to column connections, for the loading condition under consideration.

The effects of the lateral resistance provided by an embedded cap may be considered in the evaluation of horizontal movement.

The orientation of nonsymmetrical pile cross-sections shall be considered when computing the pile lateral stiffness.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in ASTM D3966.

The effects of group interaction shall be taken into account when evaluating pile group horizontal movement. When the *P-y* method of analysis is used, the values of $P$ shall be multiplied by $P$-multiplier values, $P_m$, to account for group effects. The values of $P_m$ provided in Table 10.7.2.4-1 should be used.

### C10.7.2.4

Pile foundations are subjected to lateral loads due to wind, traffic loads, bridge curvature, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles, and vertical piles are more effective against dynamic loads.

Methods of analysis that use manual computation were developed by Broms (1964a and 1964b). They are discussed in detail by Hannigan et al. (2006). Reese developed analysis methods that model the horizontal soil resistance using *P-y* curves. This analysis has been well developed and software is available for analyzing single piles and pile groups (Reese, 1986; Williams et al., 2003; and Hannigan et al., 2006).

Deep foundation horizontal movement at the foundation design stage may be analyzed using computer applications that consider soil-structure interaction. Application formulations are available that consider the total structure including pile cap, pier and superstructure (Williams et al., 2003).

If a lateral static load test is used to assess the site specific lateral resistance of a pile, information on the methods of analysis and interpretation of lateral load tests presented in the *Handbook on Design of Piles and Drilled Shafts Under Lateral Load*, Reese (1984) and *Static Testing of Deep Foundations*, Kyfor et al. (1992) should be used.

**Table 10.7.2.4-1—Pile P-Multipliers, $P_m$, for Multiple Row Shading (averaged from Hannigan et al., 2006)**

| Pile *CTC* spacing (in the direction of loading) | *P*-Multipliers, $P_m$ | | |
|---|---|---|---|
| | Row 1 | Row 2 | Row 3 and higher |
| 3*B* | 0.8 | 0.4 | 0.3 |
| 5*B* | 1.0 | 0.85 | 0.7 |

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Loading direction and spacing shall be taken as defined in Figure 10.7.2.4-1. If the loading direction for a single row of piles is perpendicular to the row (bottom detail in the Figure), a group reduction factor of less than 1.0 should only be used if the pile spacing is 5*B* or less, i.e., a $P_m$ of 0.8 for a spacing of 3*B*, as shown in Figure 10.7.2.4-1.

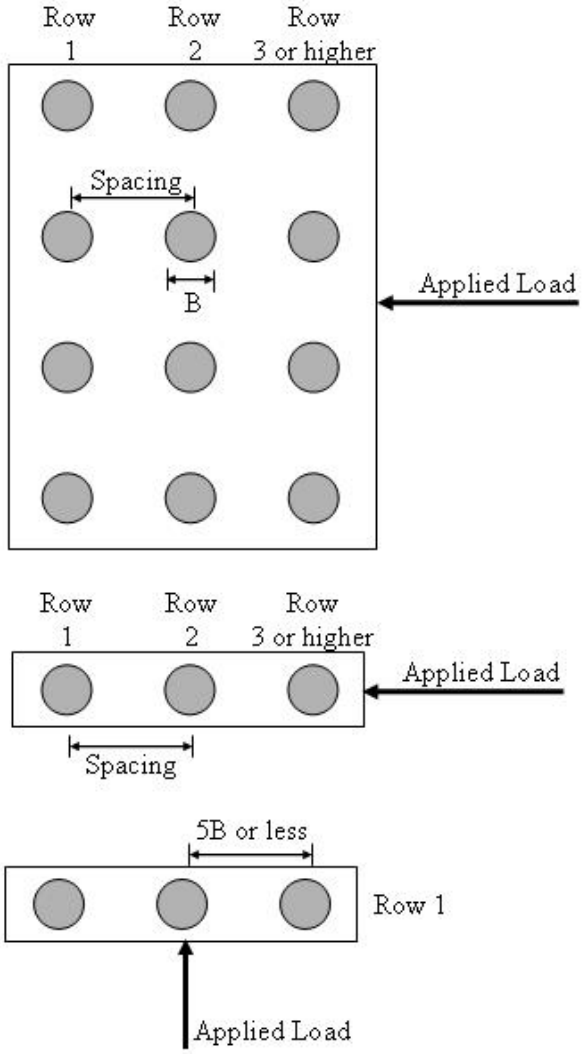

**Figure 10.7.2.4-1—Definition of Loading Direction and Spacing for Group Effects**

Since many piles are installed in groups, the horizontal resistance of the group has been studied and it has been found that multiple rows of piles will have less resistance than the sum of the single pile resistance. The front piles "shade" rows that are further back.

The P-multipliers, $P_m$, in Table 10.7.2.4-1 are a function of the center-to-center (*CTC*) spacing of piles in the group in the direction of loading expressed in multiples of the pile diameter, *B*. The values of $P_m$ in Table 10.7.2.4-1 were developed for vertical piles only.

Lateral load tests have been performed on pile groups, and multipliers have been determined that can be used in the analysis for the various rows. Those multipliers have been found to depend on the pile spacing and the row number in the direction of loading. To establish values of $P_m$ for other pile spacing values, interpolation between values should be conducted.

The multipliers are a topic of current research and may change in the future. Values from recent research have been tabulated by Hannigan et al. (2006).

Note that these *P-y* methods generally apply to foundation elements that have some ability to bend and deflect. For large diameter, relatively short foundation elements, e.g., drilled shafts or relatively short stiff piles, the foundation element rotates rather than bends, in which case strain wedge theory (Norris, 1986; Ashour et al., 1998) may be more applicable. When strain wedge theory is used to assess the lateral load response of groups of short, large diameter piles or shaft groups, group effects should be addressed through evaluation of the overlap between shear zones formed due to the passive wedge that develops in front of each shaft in the group as lateral deflection increases. Note that $P_m$ in Table 10.7.2.4-1 is not applicable if strain wedge theory is used.

Batter piles provide a much stiffer lateral response than vertical piles when loaded in the direction of the batter.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 10.7.2.5—Settlement Due to Downdrag

The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive side and tip resistance below the lowest layer contributing to the downdrag. In general, the available factored geotechnical resistance should be greater than the factored loads applied to the pile, including the downdrag, at the service limit state. In the case where it is not possible to obtain adequate geotechnical resistance below the lowest layer contributing to downdrag, e.g., piles supported by side resistance, to fully resist the downdrag, the structure should be designed to tolerate the full amount of settlement resulting from the downdrag and the other applied loads.

If adequate geotechnical resistance is available to resist the downdrag plus structure loads in the service limit state, the amount of deformation needed to fully mobilize the geotechnical resistance should be estimated, and the structure designed to tolerate the anticipated movement.

#### C10.7.2.5

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile nominal resistance to withstand the downdrag plus structure loads.

Nominal resistance may also be estimated using a dynamic method, e.g., dynamic measurements with signal matching analysis, wave equation, pile driving formula, etc., per Article 10.7.3.8, provided the side resistance within the zone contributing to downdrag is subtracted from the nominal bearing resistance determined from the dynamic method during pile installation. The side resistance within the zone contributing to downdrag may be estimated using the static analysis methods specified in Article 10.7.3.8.6, from signal matching analysis, or from instrumented pile load test results. Note that the static analysis methods may have bias that, on average, over or under predicts the side resistance. The bias of the method selected to estimate the side resistance within the downdrag zone should be taken into account as described in Article 10.7.3.3.

For the establishment of settlement tolerance limits, see Article 10.5.2.1.

#### 10.7.2.6—Lateral Squeeze

Bridge abutments supported on pile foundations driven through soft soils that are subject to unbalanced embankment fill loading shall be evaluated for lateral squeeze.

#### C10.7.2.6

Guidance on evaluating the potential for lateral squeeze and potential mitigation methods are included in Hannigan et al., (2006).

### 10.7.3—Strength Limit State Design

#### 10.7.3.1—General

For strength limit state design, the following shall be determined:

- Loads and performance requirements;
- Pile type, dimensions, and nominal bearing resistance;
- Size and configuration of the pile group to provide adequate foundation support;
- Estimated pile length to be used in the construction contract documents to provide a basis for bidding;
- A minimum pile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) depth needed to meet all of the applicable requirements identified in Article 10.7.6;
- The maximum driving resistance expected in order to reach the minimum pile penetration required, if applicable, including any soil/pile side resistance that will not contribute to the long-term nominal bearing resistance of the pile, e.g., soil contributing to downdrag, or soil that will be removed by scour;

#### C10.7.3.1

A minimum pile penetration should only be specified if needed to ensure that uplift, lateral stability, depth to resist downdrag, depth to satisfy scour concerns, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements for the service and extreme event limit states. See Article 10.7.6 for additional details. Assuming static load tests, dynamic methods, e.g., dynamic test with signal matching, wave equation, pile formulae, etc., are used during pile installation to establish when the nominal bearing resistance has been met, a minimum pile penetration should not be used to ensure that the required nominal pile bearing, i.e., compression, resistance is obtained.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- The drivability of the selected pile to achieve the required nominal axial resistance or minimum penetration with acceptable driving stresses at a satisfactory blow count per unit length of penetration; and
- The nominal structural resistance of the pile and/or pile group.

Overall stability of a pile supported foundation shall be evaluated where:

- the foundation is placed through an embankment,
- the pile foundation is located on, near or within a slope,
- the possibility of loss of foundation support through erosion or scour exists, or
- bearing strata are significantly inclined.

Unbalanced lateral forces caused by lack of overall stability or lateral squeeze should be mitigated through stabilization measures to prevent failure of the foundation, structure, and what the foundation supports.

A nominal resistance measured during driving exceeding the compressive nominal resistance required by the contract may be needed in order to reach a minimum pile penetration specified in the contract.

The drivability analysis is performed to establish whether a hammer and driving system will likely install the pile in a satisfactory manner.

**10.7.3.2—Point Bearing Piles on Rock**

*10.7.3.2.1—General*

As applied to pile compressive resistance, this Article shall be considered applicable to soft rock, hard rock, and very strong soils such as very dense glacial tills that will provide high nominal bearing resistance in compression with little penetration.

*C10.7.3.2.1*

If pile penetration into rock is expected to be minimal, the prediction of the required pile length will usually be based on the depth to rock.

A definition of hard rock that relates to measurable rock characteristics has not been widely accepted. Local or regional experience with driving piles to rock provides the most reliable definition.

In general, it is not practical to drive piles into rock to obtain significant uplift or lateral resistance. The ability to obtain sufficient uplift resistance will depend on the softness of the rock formation. Local experience should also be considered. If significant lateral or uplift foundation resistance is required, drilled shaft foundations should be considered. If it is still desired to use piles, a pile drivability study should be performed to verify the feasibility of obtaining the desired penetration into rock.

*10.7.3.2.2—Piles Driven to Soft Rock*

Soft rock that can be penetrated by pile driving shall be treated in the same manner as soil for the purpose of design for bearing resistance, in accordance with Article 10.7.3.8.

*C10.7.3.2.2*

Steel piles driven into soft rock may not require tip protection.

*10.7.3.2.3—Piles Driven to Hard Rock*

The nominal resistance of piles driven to point bearing on hard rock where pile penetration into the rock formation is minimal is controlled by the structural limit state. The nominal bearing resistance shall not exceed the

*C10.7.3.2.3*

Care should be exercised in driving piles to hard rock to avoid tip damage. The tips of steel piles driven to hard rock should be protected by high strength, cast steel tip protection.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

values obtained from Article 6.9.4.1 with the resistance factors specified in Article 6.5.4.2 and Article 6.15 for severe driving conditions. A pile-driving acceptance criteria shall be developed that will prevent pile damage. Dynamic pile measurements should be used to monitor for pile damage.

If the rock surface is reasonably flat, installation with pile tip protection should be considered. In the case of sloping rock, or when battered piles are driven to rock, greater difficulty can arise and the use of tip protection with teeth should be considered. The designer should perform a wave equation analysis to check anticipated stresses, and also consider the following to minimize the risk of pile damage during installation:

- Use a relatively small hammer. If a hammer with adjustable stroke or energy setting is used, it should be operated with a small stroke to seat the pile. The nominal axial resistance can then be proven with a few larger hammer blows.
- A large hammer should not be used if it cannot be adjusted to a low stroke. It may be impossible to detect possible toe damage if a large hammer with large stroke is used.
- For any hammer size, specify a limited number of hammer blows after the pile tip reaches the rock, and stop immediately. An example of a limiting criteria is five blows per one half inch.
- Extensive dynamic testing can be used to verify bearing resistance on a large percentage of the piles. This approach could be used to justify larger design nominal resistances.

If such measures are taken, and successful local experience is available, it may be acceptable to not conduct the dynamic pile measurements.

### 10.7.3.3—Pile Length Estimates for Contract Documents

Subsurface geotechnical information combined with static analysis methods (see Article 10.7.3.8.6), preconstruction probe pile programs (see Article 10.7.9), and/or pile load tests (see Article 10.7.3.8.2) shall be used to estimate the depth of penetration required to achieve the desired nominal bearing resistance to establish contract pile quantities. If static analysis methods are used, potential bias in the method selected should be considered when estimating the penetration depth required to achieve the desired nominal bearing resistance. Local pile driving experience shall also be considered when making pile quantity estimates. If the depth of penetration required to obtain the desired nominal bearing, i.e., compressive, resistance is less than the depth required to meet the provisions of Article 10.7.6, the minimum penetration required per Article 10.7.6 should be used as the basis for estimating contract pile quantities.

### C10.7.3.3

The estimated pile length necessary to provide the required nominal resistance is determined using a static analysis, local pile driving experience, knowledge of the site subsurface conditions, and/or results from a static pile load test program. The required pile length is often defined by the presence of an obvious bearing layer. Local pile driving experience with such a bearing layer should be strongly considered when developing pile quantity estimates.

In variable soils, a program of probe piles across the site is often used to determine variable pile order lengths. Probe piles are particularly useful when driving concrete piles. The pile penetration depth (i.e., length) used to estimate quantities for the contract should also consider requirements to satisfy other design considerations, including service and extreme event limit states, as well as minimum pile penetration requirements for lateral stability, uplift, downdrag, scour, group settlement, etc.

One solution to the problem of predicting pile length is the use of a preliminary test program at the site. Such a program can range from a very simple operation of driving a few piles to evaluate drivability, to an extensive program where different pile types are driven and static load and dynamic testing is performed. For large projects, such test programs may be very cost effective.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

In lieu of local pile driving experience, if a static analysis method is used to estimate the pile length required to achieve the desired nominal resistance for establishment of contract pile quantities, to theoretically account for method bias, the factored resistance used to determine the number of piles required in the pile group may be conservativley equated to the factored resistance estimated using the static analysis method as follows:

$$\varphi_{dyn} \times R_n = \varphi_{stat} \text{ x } R_{nstat} \qquad \text{(C10.7.3.3-1)}$$

where:

$\varphi_{dyn}$ = the resistance factor for the dynamic method used to verify pile bearing resistance during driving specified in Table 10.5.5.2.3-1
$R_n$ = the nominal pile bearing resistance (kips)
$\varphi_{stat}$ = the resistance factor for the static analysis method used to estimate the pile penetration depth required to achieve the desired bearing resistance specified in Table 10.5.5.2.3-1
$R_{nstat}$ = the predicted nominal resistance from the static analysis method used to estimate the penetration depth required (kips)

Using Eq. C10.7.3.3-1 and solving for $R_{nstat}$, use the static analysis method to determine the penetration depth required to obtain $R_{nstat}$.

The resistance factor for the static analysis method inherently accounts for the bias and uncertainty in the static analysis method. However, local experience may dictate that the penetration depth estimated using this approach be adjusted to reflect that experience. Where piles are driven to a well defined firm bearing stratum, the location of the top of bearing stratum will dictate the pile length needed, and Eq. C10.7.3.3-1 is likely not applicable.

Note that $R_n$ is considered to be nominal bearing resistance of the pile needed to resist the applied loads, and is used as the basis for determining the resistance to be achieved during pile driving, $R_{ndr}$ (see Articles 10.7.6 and 10.7.7). $R_{nstat}$ is only used in the static analysis method to estimate the pile penetration depth required.

Note that while there is a theoretical basis to this suggested approach, it can produce apparently erroneous results if attempting to use extremes in static analysis and dynamic methods, e.g., using static load test results and then using the Engineering News formula to control pile driving, or using a very inaccurate static analysis method in combination with dynamic testing and signal matching. Part of the problem is that the available resistance factors have been established in consideration of the risk and consequences of pile foundation failure rather than the risk and consequences of underrunning or overrunning pile quantities. Therefore, the approach provided in Eq. C10.7.3.3-1 should be used cautiously, especially when the difference between the resistance factors for method used to estimate pile penetration depth versus the one

used for obtaining the required nominal axial resistance is large.

### 10.7.3.4—Nominal Axial Resistance Change after Pile Driving

*10.7.3.4.1—General*

Consideration should be given to the potential for change in the nominal axial pile resistance after the end of pile driving. The effect of soil relaxation or setup should be considered in the determination of nominal axial pile resistance for soils that are likely to be subject to these phenomena.

*C10.7.3.4.1*

Soil relaxation is not a common phenomenon but more serious than setup since it represents a reduction in the reliability of the foundation.

Soil setup is a common phenomenon that can provide the opportunity for using larger nominal resistances at no increase in cost. However, it is necessary that the resistance gain be adequately proven. This is usually accomplished by restrike testing with dynamic measurements (Komurka et. al, 2003).

*10.7.3.4.2—Relaxation*

If relaxation is possible in the soils at the site the pile shall be tested in restrike after a sufficient time has elapsed for relaxation to develop.

*C10.7.3.4.2*

Relaxation is a reduction in axial pile resistance. While relaxation typically occurs at the pile tip, it can also occur along the sides of the pile (Morgano and White, 2004). It can occur in dense sands or sandy silts and in some shales. Relaxation in the sands and silts will usually develop fairly quickly after the end of driving (perhaps in only a few minutes or hours) as a result of the return of the reduced pore pressure induced by dilation of the dense sands during driving. In some shales, relaxation occurs during the driving of adjacent piles and that will be immediate. There are other shales where the pile penetrates the shale and relaxation requires perhaps as much as two weeks to develop. In some cases, the amount of relaxation can be large.

*10.7.3.4.3—Setup*

Setup in the nominal axial resistance may be used to support the applied load. Where increase in resistance due to setup is utilized, the existence of setup shall be verified after a specified length of time by re-striking the pile.

*C10.7.3.4.3*

Setup is an increase in the nominal axial resistance that develops over time predominantly along the pile shaft. Pore pressures increase during pile driving due to a reduction of the soil volume, reducing the effective stress and the shear strength. Setup may occur rapidly in cohesionless soils and more slowly in finer grained soils as excess pore water pressures dissipate. In some clays, setup may continue to develop over a period of weeks and even months, and in large pile groups it can develop even more slowly.

Setup, sometimes called “pile freeze,” can be used to carry applied load, providing the opportunity for using larger pile nominal axial resistances, if it can be proven. Signal matching analysis of dynamic pile measurements made at the end of driving and later in restrike can be an effective tool in evaluating and quantifying setup. (Komurka et al., 2003) (Bogard and Matlock, 1990).

If a wave equation or dynamic formula is used to determine the nominal pile bearing resistance on restrike, care should be used as these approaches require accurate blow count measurement which is inherently difficult at the beginning of redrive (BOR). Furthermore, the resistance factors provided in Table 10.5.5.2.3-1 for

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

driving formulas were developed for end of driving conditions and empirically have been developed based on the assumption that soil setup will occur. See Article C10.5.5.2.3 for additional discussion on this issue.

Higher degrees of confidence for the assessment of setup effects are provided by dynamic measurements of pile driving with signal matching analyses or static load tests after a sufficient wait time following pile installation.

The restrike time and frequency should be based on the time dependent strength change characteristics of the soil. The following restrike durations are recommended:

| Soil Type | Time Delay until Restrike |
|---|---|
| Clean Sands | 1 day |
| Silty Sands | 2 days |
| Sandy Silts | 3–5 days |
| Silts and Clays | 7–14 days* |
| Shales | 7 days |

* Longer times are sometimes required.

Specifying a restrike time for friction piles in fine grained soils which is too short may result in pile length overruns.

### 10.7.3.5—Groundwater Effects and Buoyancy

Nominal axial resistance shall be determined using the groundwater level consistent with that used to calculate the effective stress along the pile sides and tip. The effect of hydrostatic pressure shall be considered in the design.

### C10.7.3.5

Unless the pile is bearing on rock, the bearing resistance is primarily dependent on the effective surcharge that is directly influenced by the groundwater level. For drained loading conditions, the vertical effective stress is related to the groundwater level and thus it affects pile axial resistance. Lateral resistance may also be affected.

Buoyant forces may also act on a hollow pile or unfilled casing if it is sealed so that water does not enter the pile. During pile installation, this may affect the driving resistance (blow count) observed, especially in very soft soils.

For design purposes, anticipated changes in the groundwater level during construction and over the life of the structure should be considered with regard to its effect on pile resistance and constructability.

### 10.7.3.6—Scour

The effect of scour shall be considered in determining the minimum pile embedment and the required nominal driving resistance, $R_{ndr}$. The pile foundation shall be designed so that the pile penetration after the design scour event satisfies the required nominal axial and lateral resistance.

The resistance factors shall be those used in the design without scour. The side resistance of the material lost due to scour should be determined using a static analysis and it should not be factored, but consideration should be given to the bias of the static analysis method used to predict resistance. Method bias is discussed in Article 10.7.3.3.

### C10.7.3.6

The piles will need to be driven to the required nominal bearing resistance plus the side resistance that will be lost due to scour. The nominal resistance of the remaining soil is determined through field verification. The pile is driven to the required nominal bearing resistance plus the magnitude of the side resistance lost as a result of scour, considering the prediction method bias.

Another approach that may be used takes advantage of dynamic measurements. In this case, the static analysis method is used to determine an estimated length. During the driving of test piles, the side resistance component of the bearing resistance of pile in the scourable material may be determined by a signal matching analysis of the restrike dynamic measurements obtained when the pile tip is below

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The pile foundation shall be designed to resist debris loads occurring during the flood event in addition to the loads applied from the structure.

### 10.7.3.7—Downdrag

The foundation should be designed so that the available factored geotechnical resistance is greater than the factored loads applied to the pile, including the downdrag, at the strength limit state. The nominal pile resistance available to support structure loads plus downdrag shall be estimated by considering only the positive side and tip resistance below the lowest layer contributing to the downdrag. The pile foundation shall be designed to structurally resist the downdrag plus structure loads.

In the instance where it is not possible to obtain adequate geotechnical resistance below the lowest layer contributing to downdrag, e.g., piles supported by side resistance, to fully resist the downdrag, or if it is anticipated that significant deformation will be required to mobilize the geotechnical resistance needed to resist the factored loads including the downdrag load, the structure should be designed to tolerate the settlement resulting from the downdrag and the other applied loads as specified in Article 10.7.2.5.

the scour elevation. The material below the scour elevation must provide the required nominal resistance after scour occurs.

In some cases, the flooding stream will carry debris that will induce horizontal loads on the piles.

Additional information regarding pile design for scour is provided in Hannigan et al. (2006).

### C10.7.3.7

The static analysis procedures in Article 10.7.3.8.6 may be used to estimate the available pile nominal resistance to withstand the downdrag plus structure loads.

Nominal resistance may also be estimated using an instrumented static load test or dynamic testing during restrike with signal matching, provided the side resistance within the zone contributing to downdrag is subtracted from the resistance determined from the static load or dynamic test. The side resistance within the zone contributing to downdrag may be estimated using the static analysis methods specified in Article 10.7.3.8.6, from restrike signal matching analysis, or from instrumented static pile load test results. Note that the static analysis method may have a bias, on average over or under predicting the side resistance. The bias of the method selected to estimate the skin friction should be taken into account as described in Article C10.7.3.3.

Pile design for downdrag is illustrated in Figure C10.7.3.7-1.

where:

$R_{Sdd}$ = side resistance which must be overcome during driving through downdrag zone (kips)

$Q_p = \Sigma\gamma_i Q_i$ = factored load per pile, excluding downdrag load (kips)

$DD$ = downdrag load per pile (kips)

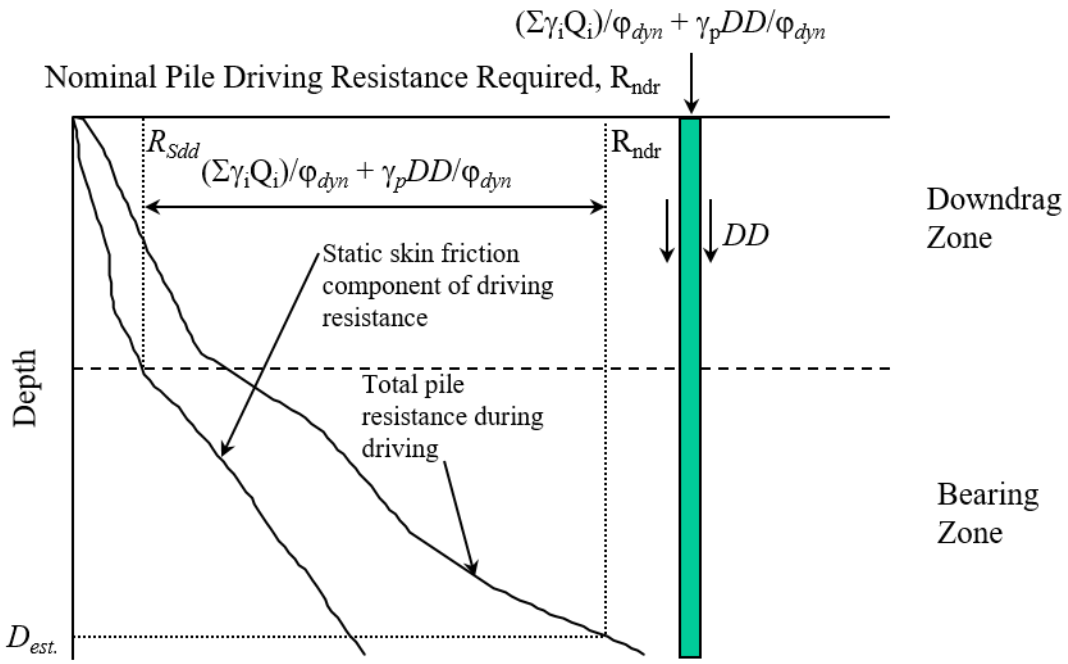
$D_{est.}$ = estimated pile length needed to obtain desired nominal resistance per pile (ft)

$\varphi_{dyn}$ = resistance factor, assuming that a dynamic method is used to estimate nominal pile resistance during installation of the pile (if a static analysis method is used instead, use $\varphi_{stat}$)

$\gamma_p$ = load factor for downdrag

The summation of the factored loads ($\Sigma\gamma_i Q_i$) should be less than or equal to the factored resistance ($\varphi_{dyn} R_n$). Therefore, the nominal resistance $R_n$ should be greater than or equal to the sum of the factored loads divided by the resistance factor $\varphi_{dyn}$. The nominal bearing resistance (kips) of the pile needed to resist the factored loads, including downdrag, is therefore taken as:

$$R_n = \frac{\left(\Sigma\gamma_i Q_i\right)}{\varphi_{dyn}} + \frac{\gamma_p DD}{\varphi_{dyn}} \qquad \text{(C10.7.3.7-1)}$$



© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The total nominal driving resistance, $R_{ndr}$ (kips), needed to obtain $R_n$, accounting for the side resistance that must be overcome during pile driving that does not contribute to the nominal resistance of the pile, is taken as:

$$R_{ndr} = R_{Sdd} + R_n \quad \text{(C10.7.3.7-2)}$$

where:
$R_{ndr}$ = nominal pile driving resistance required (kips)

Note that $R_{Sdd}$ remains unfactored in this analysis to determine $R_{ndr}$.

$Q_{Sdd}$ = skin friction which must be overcome during driving through downdrag zone
$(Sg_iQ_i)/\varphi_{dyn} + \gamma_p DD/\varphi_{dyn}$ = nominal pile resistance needed to resist all applied loads per pile, including downdrag
$Q_p = (Sg_iQ_i)$ = factored load per pile, excluding downdrag load
$Q_{DD}$ = downdrag load per pile
$D_{est.}$ = estimated pile length needed to obtain desired nominal resistance per pile
$\varphi_{dyn}$ = resistance factor, assuming that a dynamic method is used to estimate pile resistance
$\gamma_p$ = load factor for downdrag

**Figure C10.7.3.7-1—Design of Pile Foundations for Downdrag**

### 10.7.3.8—Determination of Nominal Bearing Resistance for Piles

*10.7.3.8.1—General*

Nominal pile bearing resistance should be field verified during pile installation using static load tests, dynamic tests, wave equation analysis, or dynamic formula. The resistance factor selected for design shall be based on the method used to verify pile bearing resistance as specified in Article 10.5.5.2.3. The production piles

*C10.7.3.8.1*

This Article addresses the determination of the nominal bearing (compression) resistance needed to meet strength limit state requirements, using factored loads and factored resistance values. From this design step, the number of piles and pile nominal resistance needed to resist the factored loads applied to the foundation are

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

shall be driven to the minimum blow count determined from the static load test, dynamic test, wave equation, or dynamic formula and, if required, to a minimum penetration needed for uplift, scour, lateral resistance, or other requirements as specified in Article 10.7.6. If it is determined that static load testing is not feasible and dynamic methods are unsuitable for field verification of nominal bearing resistance, the piles shall be driven to the tip elevation determined from the static analysis, and to meet other limit states as required in Article 10.7.6.

*10.7.3.8.2—Static Load Test*

If a static pile load test is used to determine the pile nominal axial resistance, the test shall not be performed less than five days after the test pile was driven unless approved by the Engineer. The load test shall follow the procedures specified in ASTM D1143, and the loading procedure should follow the Quick Load Test Procedure.

Unless specified otherwise by the Engineer, the nominal bearing resistance shall be determined from the test data as follows:

- for piles 24.0 in. or less in diameter (length of side for square piles), the davisson method;
- for piles larger than 36.0 in. in diameter (length of side for square piles), at a pile top movement, $s_f$(in.), as determined from Eq. 10.7.3.8.2-1; and
- for piles greater than 24.0 in. but less than 36.0 in. in diameter, criteria to determine the nominal bearing resistance that is linearly interpolated between the criteria determined at diameters of 24.0 and 36.0 in.

$$s_f = \frac{QL}{12\,AE} + \frac{B}{2.5} \qquad (10.7.3.8.2\text{-}1)$$

where:

$Q$ = test load (kips)
$L$ = pile length (ft)
$A$ = pile cross-sectional area (ft$^2$)
$E$ = pile modulus (ksi)
$B$ = pile diameter (length of side for square piles) (ft)

determined. Both the loads and resistance values are factored as specified in Articles 3.4.1 and 10.5.5.2.3, respectively, for this determination.

In most cases, the nominal resistance of production piles should be controlled by driving to a required blow count. In a few cases, usually piles driven into cohesive soils with little or no toe resistance and very long wait times to achieve the full pile resistance increase due to soil setup, piles may be driven to depth. However, even in those cases, a pile may be selected for testing after a sufficient waiting period, using either a static load test or a dynamic test.

In cases where the project is small and the time to achieve soil setup is large compared with the production time to install all of the piles, no field testing for the verification of nominal resistance may be acceptable.

*C10.7.3.8.2*

The Quick Load Test Procedure is preferred because it avoids problems that frequently arise when performing a static load test that cannot be completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Load Test has proven to be easily performed in the field and the results usually are satisfactory. Static load tests should be conducted to failure whenever possible and practical to extract the maximum information, particularly when correlating with dynamic tests or static analysis methods. However, if the formation in which the pile is installed may be subject to significant creep settlement, alternative procedures provided in ASTM D1143 should be considered.

The Davisson Method to determine nominal bearing resistance evaluation is performed by constructing a line on the static load test curve that is parallel to the elastic compression line of the pile. The elastic compression line is calculated by assuming equal compressive forces are applied to the pile ends. The elastic compression line is offset by a specified amount of displacement. The Davisson Method is illustrated in Figure C10.7.3.8.2-1 and described in more detail in Hannigan et al. (2006).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Driving criteria should be established in consideration of the static load test results.

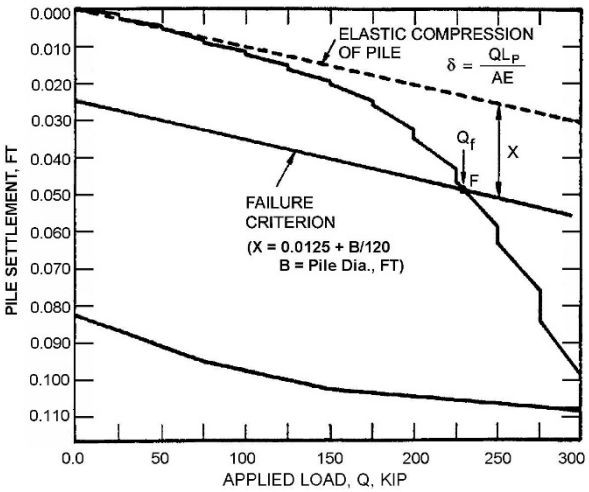


**Figure C10.7.3.8.2-1—Alternate Method Load Test Interpretation (Cheney and Chassie, 2000, modified after Davisson, 1972) Note: The failure criterion, *X*, is in feet in this figure.**

For piles with large cross-sections, i.e., diameters greater than 24.0 in., the Davisson Method will under predict the nominal pile bearing resistance.

Development of driving criteria in consideration of static load test results is described in Hannigan et al. (2006).

*10.7.3.8.3—Dynamic Testing*

Dynamic testing shall be performed according to the procedures given in ASTM D4945. If possible, the dynamic test should be performed as a restrike test if the Engineer anticipates significant time dependent strength change. The nominal pile bearing resistance shall be determined by a signal matching analysis of the dynamic pile test data if the dynamic test is used to establish the driving criteria.

*C10.7.3.8.3*

The dynamic test may be used to establish the driving criteria at the beginning of production driving. A signal matching analysis (Rausche et al., 1972) of the dynamic test data should always be used to determine bearing resistance if a static load test is not performed. See Hannigan et al. (2006) for a description of and procedures to conduct a signal matching analysis. Restrike testing should be performed if setup or relaxation is anticipated.

For example, note that it may not be possible to adjust the dynamic measurements with signal matching analysis to match the static load test results if the driving resistance at the time the dynamic measurement is taken is too large, i.e., the pile set per hammer blow is too small. In this case, adequate hammer energy is not reaching the pile tip to assess end bearing and produce an accurate match, though in such cases, the prediction will usually be very conservative. In general, a tip movement (pile set) of 0.10 to 0.15 in. is needed to provide an accurate signal matching analysis. See Hannigan et al. (2006) for additional guidance on this issue.

In cases where a significant amount of soil setup occurs and the set at the beginning of redrive (BOR) is less than 0.10 inch per blow, a more accurate nominal resistance may be obtained by combining the end bearing determined using the signal matching analysis obtained for the end of driving (EOD) with the signal matching analysis for the shaft resistance at the beginning of redrive.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Dynamic testing and interpretation of the test data should only be performed by certified, experienced testers.

*10.7.3.8.4—Wave Equation Analysis*

If a wave equation analysis is to be used to establish the driving criteria, it shall be performed based on the hammer and pile driving system to be used for pile installation.

If a wave equation analysis is used for the determination of the nominal bearing resistance, then the driving criterion (blow count) may be the value taken either at the end of driving (EOD) or at the beginning of redrive (BOR). The latter should be used where the soils exhibit significant strength changes (setup or relaxation) with time. When restrike (i.e., BOR) blow counts are taken, the hammer shall be warmed up prior to restrike testing and the blow count shall be taken as accurately as possible for the first inch of restrike.

If the wave equation is used to assess the potential for pile damage, driving stresses shall not exceed the values obtained in Article 10.7.8, using the resistance factors specified or referred to in Table 10.5.5.2.3-1. Furthermore, the blow count needed to obtain the maximum driving resistance anticipated shall be less than the maximum value established based on the provisions in Article 10.7.8.

*C10.7.3.8.4*

Note that without dynamic test results with signal matching analysis and/or pile load test data (see Articles 10.7.3.8.2 and 10.7.3.8.3), some judgment is required to use the wave equation to predict the pile bearing resistance. Unless experience in similar soils exists, the recommendations of the software provider should be used for dynamic resistance input. Key soil input values that affect the predicted nominal resistance include the soil damping and quake values, the skin friction distribution, e.g., such as could be obtained from a static pile bearing analysis, and the anticipated amount of soil setup or relaxation. The actual hammer performance is a variable that can only be accurately assessed through dynamic measurements, though field observations such as hammer stroke or measured ram velocity can and should be used to improve the accuracy of the wave equation prediction.

In general, improved prediction accuracy of nominal bearing resistance is obtained when targeting the driving criteria at BOR conditions, if soil setup or relaxation is anticipated. Using the wave equation to predict nominal bearing resistance from EOD blow counts requires that an accurate estimate of the time-dependent changes in bearing resistance due to soil setup or relaxation be made. This is generally difficult to do unless site-specific, longer-term measurements of bearing resistance from static load tests or dynamic measurements with signal matching are available. Hence, driving criteria based on BOR measurements are recommended when using the wave equation for driving criteria development.

A wave equation analysis should also be used to evaluate pile drivability during design.

*10.7.3.8.5—Dynamic Formula*

If a dynamic formula is used to establish the driving criterion, the FHWA Gates Formula (Eq. 10.7.3.8.5-1) should be used. The nominal pile resistance as measured during driving using this method shall be taken as:

$$R_{ndr} = 1.75\sqrt{E_d}\log_{10}(10N_b) - 100 \qquad (10.7.3.8.5\text{-}1)$$

where:

$R_{ndr}$ = nominal pile driving resistance measured during pile driving (kips)

$E_d$ = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the actual stroke (ft-lb)

$N_b$ = Number of hammer blows for 1.0 in. of pile permanent set (blows/in.)

*C10.7.3.8.5*

It is preferred to use more accurate methods such as wave equation or dynamic testing with signal matching to establish driving criteria (i.e., blow count). However, driving formulas have been in use for many years. Therefore, driving formulas are provided as an option for the development of driving criteria.

Two dynamic formulas are provided here for the Engineer. If a dynamic formula is used for either determination of the nominal resistance or the driving criterion, the FHWA Modified Gates formula is preferred over the Engineering News formula. It is discussed further in the Design and Construction of Driven Pile Foundations (Hannigan et al., 2006). Note that the units in the FHWA Gates formula are not consistent. The specified units in Eq. 10.7.3.8.5-1 must be used.

The Engineering News formula in its traditional form contains a factor of safety of 6.0. For LRFD applications, to produce a nominal resistance, the factor of safety has been removed. As is true of the FHWA Gates formula,

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The Engineering News formula, modified to predict a nominal bearing resistance, may be used. The nominal pile resistance using this method shall be taken as:

$$R_{ndr} = \frac{12E_d}{(s+0.1)} \quad (10.7.3.8.5\text{-}2)$$

where:

$R_{ndr}$ = nominal pile resistance measured during driving (kips)
$E_d$ = developed hammer energy. This is the kinetic energy in the ram at impact for a given blow. If ram velocity is not measured, it may be assumed equal to the potential energy of the ram at the height of the stroke, taken as the ram weight times the stroke (ft-kips)
$s$ = pile permanent set (in.)

If a dynamic formula other than those provided herein is used, it shall be calibrated based on measured load test results to obtain an appropriate resistance factor, consistent with Article C10.5.5.2.

If a drivability analysis is not conducted, for steel piles, design stresses shall be limited as specified in Article 6.15.2.

Dynamic formulas should not be used when the required nominal resistance exceeds 600 kips.

the units specified in Eq. 10.7.3.8.5-2 must be used for the Engineering News formula. See Allen (2005; 2007) for additional discussion on the development of the Engineering News formula and its modification to produce a nominal resistance.

Driving formula should only be used to determine end of driving blow count criteria. These driving formula are empirically based on pile load test results, and therefore inherently include some degree of soil setup or relaxation (see Allen, 2007).

As the required nominal bearing resistance increases, the reliability of dynamic formulas tends to decrease. The FHWA Gates formula tends to underpredict pile nominal resistance at higher resistances. The Engineering News formula tends to become unconservative as the nominal pile resistance increases. If other driving formulas are used, the limitation on the maximum driving resistance to be used should be based upon the limits for which the data is considered reliable, and any tendency of the formula to over or under predict pile nominal resistance.

*10.7.3.8.6—Static Analysis*

*10.7.3.8.6a—General*

Where a static analysis prediction method is used to determine pile installation criteria, i.e., for bearing resistance, the nominal pile resistance shall be factored at the strength limit state using the resistance factors in Table 10.5.5.2.3-1 associated with the method used to compute the nominal bearing resistance of the pile. The factored nominal bearing resistance of piles, $R_R$, may be taken as:

$$R_R = \varphi R_n \quad (10.7.3.8.6a\text{-}1)$$

or:

$$R_R = \varphi R_n = \varphi_{stat} R_p + \varphi_{stat} R_s \quad (10.7.3.8.6a\text{-}2)$$

in which:

*C10.7.3.8.6a*

While the most common use of static analysis methods is solely for estimating pile quantities, a static analysis may be used to establish pile installation criteria if dynamic methods are determined to be unsuitable for field verification of nominal bearing resistance. This is applicable on projects where pile quantities are relatively small, pile loads are relatively low, and/or where the setup time is long so that restrike testing would require an impractical wait-period by the Contractor on the site, e.g., soft silts or clays where a large amount of setup is anticipated.

For use of static analysis methods for contract pile quantity estimation, see Article 10.7.3.3.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$R_p = q_p A_p \qquad (10.7.3.8.6a\text{-}3)$$

$$R_s = q_s A_s \qquad (10.7.3.8.6a\text{-}4)$$

where:

$\varphi_{stat}$ = resistance factor for the bearing resistance of a single pile specified in Article 10.5.5.2.3
$R_p$ = pile tip resistance (kips)
$R_s$ = pile side resistance (kips)
$q_p$ = unit tip resistance of pile (ksf)
$q_s$ = unit side resistance of pile (ksf)
$A_s$ = surface area of pile side ($ft^2$)
$A_p$ = area of pile tip ($ft^2$)

Both total stress and effective stress methods may be used, provided the appropriate soil strength parameters are available. The resistance factors for the side resistance and tip resistance, estimated using these methods, shall be as specified in Table 10.5.5.2.3-1. The limitations of each method as described in Article C10.5.5.2.3 should be applied in the use of these static analysis methods.

*10.7.3.8.6b—α-Method*

The α-method, based on total stress, may be used to relate the adhesion between the pile and clay to the undrained strength of the clay. For this method, the nominal unit side resistance, in ksf, shall be taken as:

$$q_s = \alpha S_u \qquad (10.7.3.8.6b\text{-}1)$$

where:

$S_u$ = undrained shear strength (ksf)
$\alpha$ = adhesion factor applied to $S_u$ (dim)

The adhesion factor for this method, α, shall be assumed to vary with the value of the undrained strength, $S_u$, as shown in Figure 10.7.3.8.6b-1.

*C10.7.3.8.6b*

The α-method has been used for many years and gives reasonable results for both displacement and nondisplacement piles in clay.

In general, this method assumes that a mean value of $S_u$ will be used. It may not always be possible to establish a mean value, as in many cases, data are too limited to reliably establish the mean value. The Engineer should apply engineering judgment and local experience as needed to establish an appropriate value for design (see Article C10.4.6).

For H-piles, the perimeter or "box" area should generally be used to compute the surface area of the pile side.

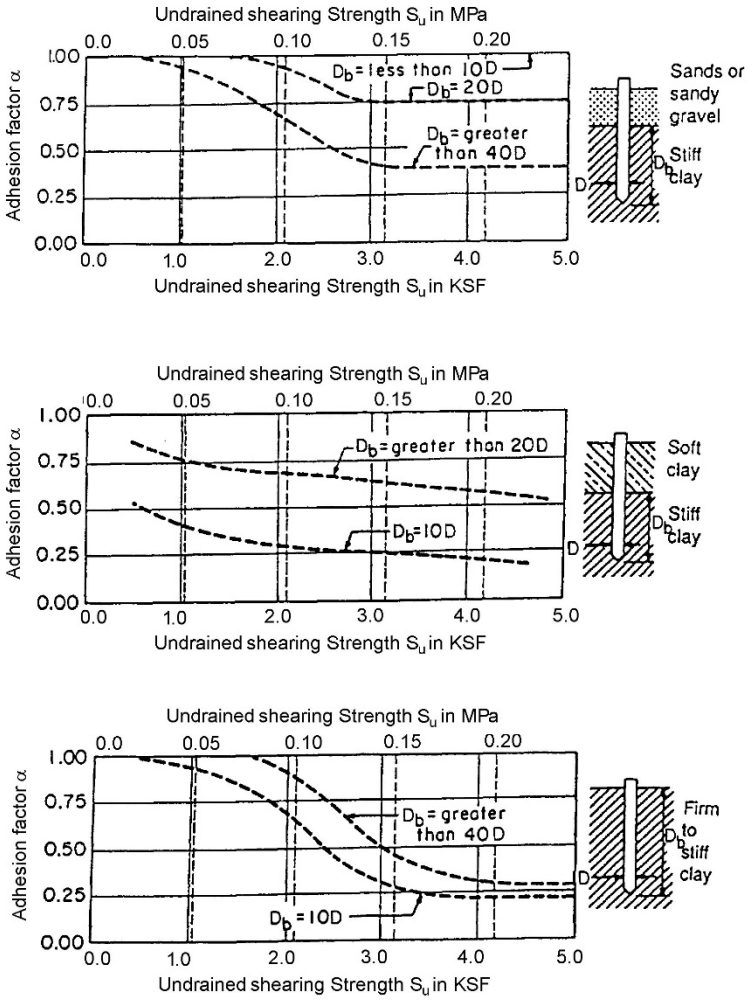

**Figure 10.7.3.8.6b-1—Design Curves for Adhesion Factors for Piles Driven into Clay Soils after Tomlinson (1980)**

*10.7.3.8.6c—β-Method*

The β-method, based on effective stress, may be used for predicting side resistance of prismatic piles. The nominal unit skin friction for this method, in ksf, shall be related to the effective stresses in the ground as:

$$q_s = \beta\sigma'_v \qquad (10.7.3.8.6c\text{-}1)$$

where:

$\sigma'_v$ = vertical effective stress (ksf)
β = a factor taken from Figure 10.7.3.8.6c-1

*C10.7.3.8.6c*

The β-method has been found to work best for piles in normally consolidated and lightly overconsolidated clays. The method tends to overestimate side resistance of piles in heavily overconsolidated soils. Esrig and Kirby (1979) suggested that for heavily overconsolidated clays, the value of β should not exceed two.

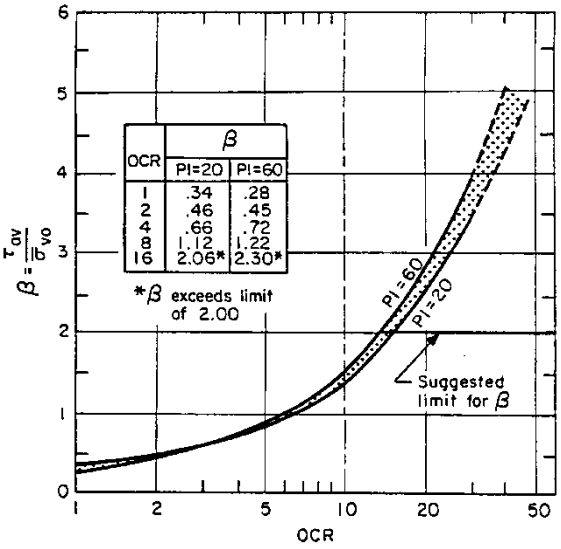

**Figure 10.7.3.8.6c-1—β Versus OCR for Displacement Piles after Esrig and Kirby (1979)**

*10.7.3.8.6d—λ-Method*

The λ-method, based on effective stress (though it does contain a total stress parameter), may be used to relate the unit side resistance, in ksf, to passive earth pressure. For this method, the unit skin friction shall be taken as:

$$q_s = \lambda(\sigma'_v + 2S_u) \qquad (10.7.3.8.6d\text{-}1)$$

where:

$\sigma'_v + 2S_u$ = passive lateral earth pressure (ksf)
$\sigma'_v$ = the effective vertical stress at midpoint of soil layer under consideration (ksf)
$\lambda$ = an empirical coefficient taken from Figure 10.7.3.8.6d-1 (dim)

*C10.7.3.8.6d*

The value of λ decreases with pile length and was found empirically by examining the results of load tests on steel pipe piles.

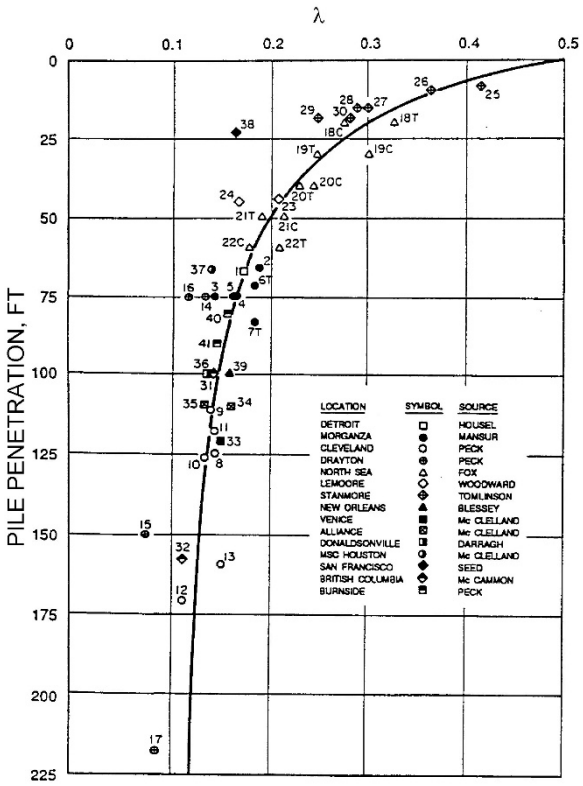

**Figure 10.7.3.8.6d-1—λ Coefficient for Driven Pipe Piles after Vijayvergiya and Focht (1972)**

*10.7.3.8.6e—Tip Resistance in Cohesive Soils*

The nominal unit tip resistance of piles in saturated clay, in ksf, shall be taken as:

$$q_p = 9S_u \qquad (10.7.3.8.6e\text{-}1)$$

where:

$S_u$ = undrained shear strength of the clay near the pile tip (ksf)

*10.7.3.8.6f—Nordlund/Thurman Method in Cohesionless Soils*

This effective stress method should be applied only to sands and nonplastic silts. The nominal unit side resistance, $q_s$, for this method, in ksf, shall be taken as:

$$q_s = K_\delta C_F \sigma'_v \frac{\sin(\delta + \omega)}{\cos\ \omega} \qquad (10.7.3.8.6f\text{-}1)$$

where:

$K_\delta$ = coefficient of lateral earth pressure at mid-point of soil layer under consideration from Figures 10.7.3.8.6f-1 through 10.7.3.8.6f-4 (dim)

*C10.7.3.8.6f*

Detailed design procedures for the Nordlund/Thurman method are provided in Hannigan et al. (2006). This method was derived based on load test data for piles in sand. In practice, it has been used for gravelly soils as well.

The effective overburden stress is not limited in Eq. 10.7.3.8.6f-1.

For H-piles, the perimeter or "box" area should generally be used to compute the surface area of the pile side.

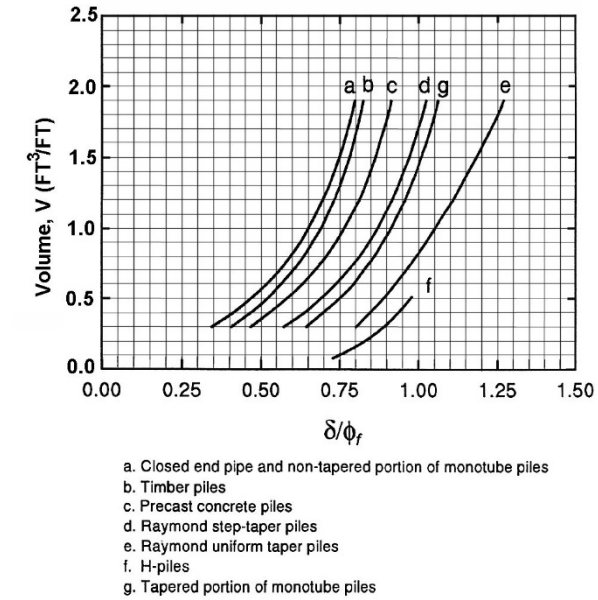

**Figure 10.7.3.8.6f-6—Relation of $\delta/\phi_f$ and Pile Displacement, *V*, for Various Types of Piles (Hannigan et al., 2006 after Nordlund, 1979)**

The nominal unit tip resistance, $q_p$, in ksf by the Nordlund/Thurman method shall be taken as:

$$q_p = \alpha_t N'_q \sigma'_v \leq q_L \qquad (10.7.3.8.6f\text{-}2)$$

where:

$\alpha_t$ = coefficient from Figure 10.7.3.8.6f-7 (dim)
$N'_q$ = bearing capacity factor from Figure 10.7.3.8.6f-8
$\sigma'_v$ = effective overburden stress at pile tip (ksf) ≤3.2 ksf
$q_L$ = limiting unit tip resistance from Figure 10.7.3.8.6f-9

If the friction angle, $\phi_f$, is estimated from average, corrected *SPT* blow counts, $N1_{60}$, the $N1_{60}$ values should be averaged over the zone from the pile tip to two diameters below the pile tip.

*10.7.3.8.6g—Using SPT or CPT in Cohesionless Soils*

*C10.7.3.8.6g*

These methods shall be applied only to sands and nonplastic silts.

The nominal unit tip resistance for the Meyerhof method, in ksf, for piles driven to a depth $D_b$ into a cohesionless soil stratum shall be taken as:

$$q_p = \frac{0.8(N1_{60})D_b}{D} \le q_\ell \qquad (10.7.3.8.6g\text{-}1)$$

where:

$N1_{60}$ = representative *SPT* blow count near the pile tip corrected for overburden pressure as specified in Article 10.4.6.2.4 (blows/ft)
$D$ = pile width or diameter (ft)
$D_b$ = depth of penetration into bearing strata (ft)
$q_\ell$ = limiting pile tip resistance (ksf)

$q_\ell$ shall be taken as eight times the value of $N1_{60}$ for sands and six times the value of $N1_{60}$ for nonplastic silt (ksf).

The nominal side resistance of piles in cohesionless soils for the Meyerhof method, in ksf, shall be taken as:

- For driven displacement piles:

$$q_s = \frac{\overline{N}1_{60}}{25} \qquad (10.7.3.8.6g\text{-}2)$$

- For nondisplacement piles, e.g., steel H-piles:

$$q_s = \frac{\overline{N}1_{60}}{50} \qquad (10.7.3.8.6g\text{-}3)$$

where:

$q_s$ = unit side resistance for driven piles (ksf)
$\overline{N}1_{60}$ = average corrected *SPT*-blow count along the pile side (blows/ft)

Tip resistance, $q_p$, for the Nottingham and Schmertmann method, in ksf, shall be determined as shown in Figure 10.7.3.8.6g-1.

In which:

$$q_p = \frac{q_{c1} + q_{c2}}{2} \qquad (10.7.3.8.6g\text{-}4)$$

where:

$q_{c1}$ = average $q_c$ over a distance of $yD$ below the pile tip (path a-b-c); sum $q_c$ values in both the downward (path a-b) and upward (path b-c)

In-situ tests are widely used in cohesionless soils because obtaining good quality samples of cohesionless soils is very difficult. In-situ test parameters may be used to estimate the tip resistance and side resistance of piles.

Two frequently used in-situ test methods for predicting pile axial resistance are the standard penetration test (*SPT*) method (Meyerhof, 1976) and the cone penetration test (*CPT*) method (Nottingham and Schmertmann, 1975).

Displacement piles, which have solid sections or hollow sections with a closed end, displace a relatively large volume of soil during penetration. Nondisplacement piles usually have relatively small cross-sectional areas, e.g., steel H-piles and open-ended pipe piles that have not yet plugged. Plugging occurs when the soil between the flanges in a steel H-pile or the soil in the cylinder of an open-ended steel pipe pile adheres fully to the pile and moves down with the pile as it is driven.

*CPT* may be used to determine:

- The cone penetration resistance, $q_c$, which may be used to determine the tip resistance of piles, and
- Sleeve friction, $f_s$, which may be used to determine the side resistance.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

directions; use actual $q_c$ values along path a-b and the minimum path rule along path b-c; compute $q_{c1}$ for $y$-values from 0.7 to 4.0 and use the minimum $q_{c1}$ value obtained (ksf)

$q_{c2}$ = average $q_c$ over a distance of 8$D$ above the pile tip (path c-e); use the minimum path rule as for path b-c in the $q_{c1}$, computations; ignore any minor "x" peak depressions if in sand but include in minimum path if in clay (ksf)

The minimum average cone resistance between 0.7 and four pile diameters below the elevation of the pile tip shall be obtained by a trial and error process, with the use of the minimum-path rule. The minimum-path rule shall also be used to find the value of cone resistance for the soil for a distance of eight pile diameters above the tip. The two results shall be averaged to determine the pile tip resistance.

The nominal side resistance of piles for this method, in kips, shall be taken as:

$$R_s = K_{s,c}\left[\sum_{i=1}^{N_1}\left(\frac{L_i}{8D_i}\right) f_{si} a_{si} h_i + \sum_{i=1}^{N_2} f_{si} a_{si} h_i\right] \quad \text{(10.7.3.8.6g-5)}$$

where:

$K_{s,c}$ = correction factors: $K_c$ for clays and $K_s$ for sands from Figure 10.7.3.8.6g-2 (dim)

$L_i$ = depth to middle of length interval at the point considered (ft)

$D_i$ = pile width or diameter at the point considered (ft)

$f_{si}$ = unit local sleeve friction resistance from *CPT* at the point considered (ksf)

$a_{si}$ = pile perimeter at the point considered (ft)

$h_i$ = length interval at the point considered (ft)

$N_1$ = number of intervals between the ground surface and a point 8$D$ below the ground surface

$N_2$ = number of intervals between 8$D$ below the ground surface and the tip of the pile

This process is described in Nottingham and Schmertmann (1975).

For a pile of constant cross-section (nontapered), Eq. 10.7.3.8.6g-5 can be written as:

$$R_s = K_{s,c}\left[\frac{a_s}{8D}\sum_{i=1}^{N_1} L_i f_{si} h_i + a_s \sum_{i=1}^{N_2} f_{si} h_i\right] \quad \text{(C10.7.3.8.6g-1)}$$

If, in addition to the pile being prismatic, $f_s$ is approximately constant at depths below 8$D$, Eq. C10.7.3.8.6g-1 can be simplified to:

$$R_s = K_{s,c}\left[a_s f_s (Z - 4D)\right] \quad \text{(C10.7.3.8.6g-2)}$$

where:

$Z$ = total embedded pile length (ft)

### 10.7.3.9—Resistance of Pile Groups in Compression

For pile groups in clay, the nominal bearing resistance of the pile group shall be taken as the lesser of:

- The sum of the individual nominal resistances of each pile in the group, or
- The nominal resistance of an equivalent pier consisting of the piles and the block of soil within the area bounded by the piles.

If the cap is not in firm contact with the ground and if the soil at the surface is soft, the individual nominal resistance of each pile shall be multiplied by an efficiency factor η, taken as:

- η = 0.65 for a center-to-center spacing of 2.5 diameters,
- η = 1.0 for a center-to-center spacing of 6.0 diameters.

For intermediate spacings, the value of η should be determined by linear interpolation.

If the cap is in firm contact with the ground, no reduction in efficiency shall be required. If the cap is not in firm contact with the ground and if the soil is stiff, no reduction in efficiency shall be required.

The nominal bearing resistance of pile groups in cohesionless soil shall be the sum of the resistance of all the piles in the group. The efficiency factor, η, shall be 1.0 where the pile cap is or is not in contact with the ground for a center-to-center pile spacing of 2.5 diameters or

### C10.7.3.9

The equivalent pier approach checks for block failure and is generally only applicable for pile groups within cohesive soils. For pile groups in cohesionless soils, the sum of the nominal resistances of the individual piles always controls the group resistance.

When analyzing the equivalent pier, the full shear strength of the soil should be used to determine the friction resistance. The total base area of the equivalent pier should be used to determine the end bearing resistance.

In cohesive soils, the nominal resistance of a pile group depends on whether the cap is in firm contact with the ground beneath. If the cap is in firm contact, the soil between the pile and the pile group behave as a unit.

At small pile spacings, a block type failure mechanism may prevail, whereas individual pile failure may occur at larger pile spacings. It is necessary to check for both failure mechanisms and design for the case that yields the minimum capacity.

For a pile group of width $X$, length $Y$, and depth $Z$, as shown in Figure C10.7.3.9-1, the bearing capacity for block failure, in kips, is given by:

$$Q_g = (2X + 2Y)Z\overline{S_u} + XYN_cS_u \qquad \text{(C10.7.3.9-1)}$$

in which:

for $\frac{Z}{X} \le 2.5$:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

greater. The resistance factor is the same as that for single piles, as specified in Table 10.5.5.2.3-1.

For pile groups in clay or sand, if a pile group is tipped in a strong soil deposit overlying a weak deposit, the block bearing resistance shall be evaluated with consideration to pile group punching as a group into the underlying weaker layer. The methods in Article 10.6.3.1.2a of determining bearing resistance of a spread footing in a strong layer overlying a weaker layer shall apply, with the notional footing located as shown in Article 10.7.2.3.

$$N_c = 5\left(1 + \frac{0.2X}{Y}\right)\left(1 + \frac{0.2Z}{X}\right) \qquad \text{(C10.7.3.9-2)}$$

for $\frac{Z}{X} > 2.5$:

$$N_c = 7.5\left(1 + \frac{0.2X}{Y}\right) \qquad \text{(C10.7.3.9-3)}$$

where:

$\overline{S_u}$ = average undrained shear strength along the depth of penetration of the piles (ksf)

$S_u$ = undrained shear strength at the base of the group (ksf)

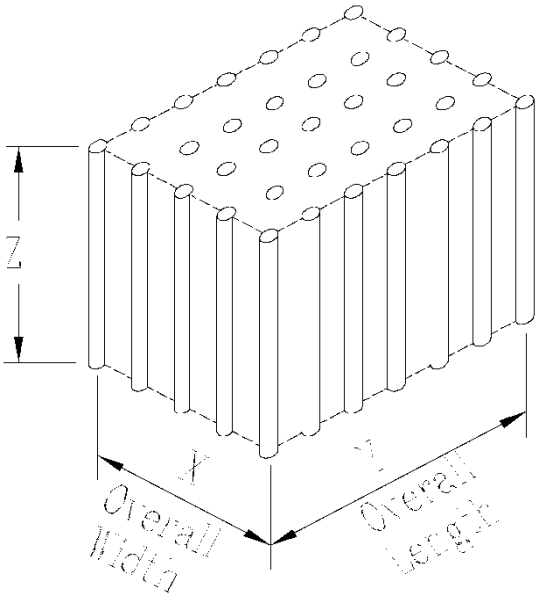

**Figure C10.7.3.9-1—Pile Group Acting as a Block Foundation**

### 10.7.3.10—Uplift Resistance of Single Piles

Uplift on single piles shall be evaluated when tensile forces are present. The factored nominal tensile resistance of the pile due to soil failure shall be greater than the factored pile loads.

The nominal uplift resistance of a single pile should be estimated in a manner similar to that for estimating the side resistance of piles in compression specified in Article 10.7.3.8.6.

Factored uplift resistance in kips shall be taken as:

$$R_R = \varphi R_n = \varphi_{up} R_s \qquad \text{(10.7.3.10-1)}$$

### C10.7.3.10

The factored load effect acting on any pile in a group may be estimated using the traditional elastic strength of materials procedure for a cross-section under thrust and moment. The cross-sectional properties should be based on the pile as a unit area.

Note that the resistance factor for uplift already is reduced to 80 percent of the resistance factor for static side resistance. Therefore, the side resistance estimated based on Article 10.7.3.8.6 does not need to be reduced to account for uplift effects on side resistance.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

where:

$R_s$ = nominal uplift resistance due to side resistance (kips)
$\varphi_{up}$ = resistance factor for uplift resistance specified in Table 10.5.5.2.3-1

Nominal uplift resistance of single piles may be determined by static load test or by dynamic test with signal matching. If a static uplift test is to be performed, it shall follow the procedures specified in ASTM D3689. Dynamic tests with signal matching, if conducted, shall be performed as specified in Article 10.7.3.8.3. If dynamic tests with signal matching are used to determine uplift, a maximum of 80 percent of the uplift determined from the dynamic test should be used.

The static pile uplift load test(s) should be used to calibrate the static analysis method, i.e., back calculate soil properties, to adjust the calculated uplift resistance for variations in the stratigraphy. The minimum penetration criterion to obtain the desired uplift resistance should be based on the calculated uplift resistance using the static pile uplift load test results.

Static uplift tests should be evaluated using a modified Davisson Method as described in Hannigan et al. (2006).

If using dynamic tests with signal matching to determine uplift resistance, it may be difficult to separate the measured end bearing resistance from the side resistance acting on the bottom section of the pile, especially if the soil stiffness at the pile tip is not significantly different from the soil stiffness acting on the sides of the pile near the pile tip. If it is not clear what is end bearing and what is side friction near the pile tip, the side resistance acting on the bottom pile element should be ignored when estimating uplift resistance using this method. If the pile length is shorter than 30 ft. in length, caution should be exercised when using dynamic tests with signal matching to estimate uplift.

### 10.7.3.11—Uplift Resistance of Pile Groups

The nominal uplift resistance of pile groups shall be evaluated when the foundation is subjected to uplift loads.

Pile group factored uplift resistance, in kips, shall be taken as:

$$R_R = \varphi R_n = \varphi_{ug} R_{ug} \qquad (10.7.3.11\text{-}1)$$

where:

$\varphi_{ug}$ = resistance factor specified in Table 10.5.5.2.3-1
$R_{ug}$ = nominal uplift resistance of the pile group (kips)

The nominal uplift resistance, $R_{ug}$, of a pile group shall be taken as the lesser of:

- the sum of the individual pile uplift resistance, or
- the uplift resistance of the pile group considered as a block.

For pile groups in cohesionless soil, the weight of the block that will be uplifted shall be determined using a spread of load of 1$H$ in 4$V$ from the base of the pile group taken from Figure 10.7.3.11-1. Buoyant unit weights shall be used for soil below the groundwater level.

In cohesive soils, the block used to resist uplift in undrained shear shall be taken from Figure 10.7.3.11-2.

### C10.7.3.11

A net uplift force can act on the foundation. An example of such a load is the construction load induced during the erection of concrete segmental girder bridges.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The nominal group uplift resistance may be taken as:

$$R_n = R_{ug} = (2XZ + 2YZ)\bar{S}_u + W_g \qquad (10.7.3.11\text{-}2)$$

where:

$X$ = width of the group, as shown in Figure 10.7.3.11-2 (ft)
$Y$ = length of the group, as shown in Figure 10.7.3.11-2 (ft)
$Z$ = depth of the block of soil below pile cap taken from Figure 10.7.3.11-2 (ft)
$\bar{S}_u$ = average undrained shear strength along the sides of the pile group (ksf)
$W_g$ = weight of the block of soil, piles, and pile cap (kips)

The resistance factor for the nominal group uplift resistance, $R_{ug}$, determined as the sum of the individual pile resistances, shall be taken as the same as that for the uplift resistance of single piles as specified in Table 10.5.5.2.3-1.

The resistance factor for the uplift resistance of the pile group considered as a block shall be taken as specified in Table 10.5.5.2.3-1 for pile groups in all soils.

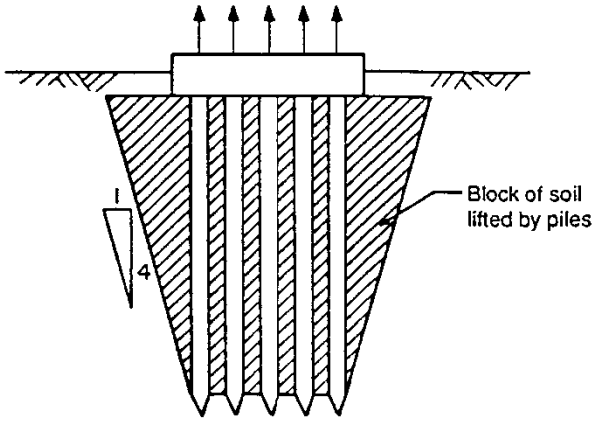

**Figure 10.7.3.11-1—Uplift of Group of Closely Spaced Piles in Cohesionless Soils after Tomlinson (1987)**

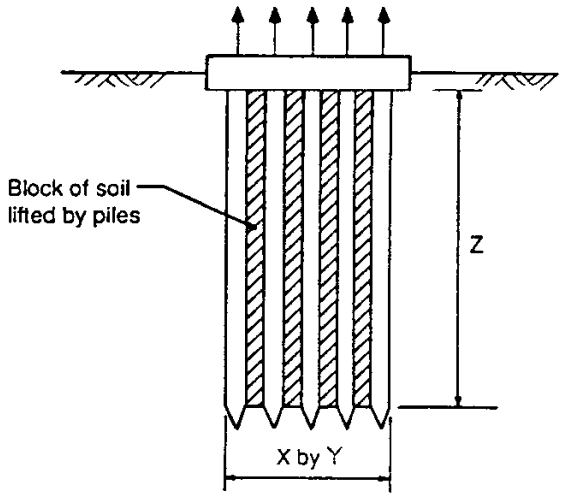

**Figure 10.7.3.11-2—Uplift of Group of Piles in Cohesive Soils after Tomlinson (1987)**

### 10.7.3.12—Nominal Lateral Resistance of Pile Foundations

The nominal resistance of pile foundations to lateral loads shall be evaluated based on both geomaterial and structural properties. The lateral soil resistance along the piles should be modeled using *P-y* curves developed for the soils at the site.

The applied loads shall be factored loads and they must include both lateral and axial loads. The analysis may be performed on a representative single pile with the appropriate pile top boundary condition or on the entire pile group. The *P-y* curves shall be modified for group effects. The *P*-multipliers in Table 10.7.2.4-1 should be used to modify the curves. If the pile cap will always be embedded, the *P-y* lateral resistance of the soil on the cap face may be included in the nominal lateral resistance.

The minimum penetration of the piles below ground (see Article 10.7.6) required in the contract should be established such that fixity is obtained. For this determination, the loads applied to the pile are factored as specified in Section 3, and a soil resistance factor of 1.0 shall be used as specified in Table 10.5.5.2.3-1.

If fixity cannot be obtained, additional piles should be added, larger diameter piles used if feasible to drive them to the required depth, or a wider spacing of piles in the group should be considered to provide the necessary lateral resistance. Batter piles may be added to provide the lateral resistance needed, unless downdrag is anticipated. If downdrag is anticipated, batter piles should not be used. The design procedure, if fixity cannot be obtained, should take into consideration the lack of fixity of the pile.

Lateral resistance of single piles may be determined by static load test. If a static lateral load test is to be performed, it shall follow the procedures specified in ASTM D3966.

### C10.7.3.12

Pile foundations are subjected to lateral loads due to wind, traffic loads, bridge curvature, stream flow, vessel or traffic impact and earthquake. Batter piles are sometimes used but they are somewhat more expensive than vertical piles and vertical piles are more effective against dynamic loads.

Additional details regarding methods of analysis using *P-y* curves, both for single piles and pile groups, are provided in Article 10.7.2.4. As an alternative to *P-y* analysis, strain wedge theory may be used (see Article 10.7.2.4).

When this analysis is performed, the loads are factored since the strength limit state is under consideration, but the resistances as represented by the *P-y* curves are not factored since they already represent the ultimate condition.

The strength limit state for lateral resistance is only structural (see Sections 5 and 6 for structural limit state design requirements), though the determination of pile fixity is the result of soil-structure interaction. A failure of the soil does not occur; the soil will continue to displace at constant or slightly increasing resistance. Failure occurs when the pile reaches the structural limit state, and this limit state is reached, in the general case, when the nominal combined bending and axial resistance is reached.

If the lateral resistance of the soil in front of the pile cap is included in the lateral resistance of the foundation, the effect of soil disturbance resulting from construction of the pile cap should be considered. In such cases, the passive resistance may need to be reduced to account for the effects of disturbance.

For information on analysis and interpretation of load tests, see Article 10.7.2.4.

### 10.7.3.13—Pile Structural Resistance

*10.7.3.13.1—Steel Piles*

The nominal axial compression resistance in the structural limit state for piles loaded in compression shall be as specified in Article 6.9.4.1 for noncomposite piles and Article 6.9.5.1 for composite piles. If the pile is fully embedded, λ in Eq. 6.9.5.1-1 shall be taken as zero.

The nominal axial resistance of horizontally unsupported noncomposite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.4.1.1-1 or 6.9.4.1.1-2. The nominal axial resistance of horizontally unsupported composite piles that extend above the ground surface in air or water shall be determined from Eqs. 6.9.5.1-1 or 6.9.5.1-2.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factors for the compression limit state are specified in Article 6.5.4.2.

*C10.7.3.13.1*

Composite members refer to steel pipe piles that are filled with concrete.

The effective length given in Article C10.7.3.13.4 is an empirical approach to determining effective length. Computer methods are now available that can determine the axial resistance of a laterally unsupported compression member using a *P*-Δ analysis that includes a numerical representation of the lateral soil resistance (Williams et al., 2003). These methods are preferred over the empirical approach in Article C10.7.3.13.4.

*10.7.3.13.2—Concrete Piles*

The nominal axial compression resistance for concrete piles and prestressed concrete piles shall be as specified in Article 5.6.4.4.

The nominal axial compression resistance for concrete piles that are laterally unsupported in air or water shall be determined using the procedures given in Articles 5.6.4.3 and 4.5.3.2. The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

The resistance factor for the compression limit state for concrete piles shall be that given in Article 5.5.4.2 for concrete loaded in axial compression.

*C10.7.3.13.2*

Article 5.6.4 includes specified limits on longitudinal reinforcement, spirals and ties. Methods are given for determining nominal axial compression resistance but they do not include the nominal axial compression resistance of prestressed members. Compression members are usually prestressed only where they are subjected to high levels of flexure. Therefore, a method of determining nominal axial compression resistance is not given.

Article 5.6.4.5 specifically permits an analysis based on equilibrium and strain compatibility. Methods are also available for performing a stability analysis (Williams et al., 2003).

*10.7.3.13.3—Timber Piles*

The nominal axial compression resistance for timber piles shall be as specified in Article 8.8.2. The methods presented there include both laterally supported and laterally unsupported members.

The effective length of laterally unsupported piles should be determined based on the provisions in Article 10.7.3.13.4.

*C10.7.3.13.3*

Article 8.5.2.3 requires that a reduction factor for long term loads of 0.75 be multiplied times the resistance factor for Strength Load Combination IV.

*10.7.3.13.4—Buckling and Lateral Stability*

In evaluating stability, the effective length of the pile shall be equal to the laterally unsupported length, plus an embedded depth to fixity.

The potential for buckling of unsupported pile lengths and the determination of stability under lateral loading should be evaluated by methods that consider soil-structure interaction as specified in Article 10.7.3.12.

*C10.7.3.13.4*

For preliminary design, the depth to fixity below the ground, in ft, may be taken as:

- For clays:

$$1.4\,[E_p\,I_w / E_s\,]^{0.25} \qquad \text{(C10.7.3.13.4-1)}$$

- For sands:

$$1.8\,[E_p\,I_w / n_h\,]^{0.2} \qquad \text{(C10.7.3.13.4-2)}$$

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

where:

$E_p$ = modulus of elasticity of pile (ksi)
$I_w$ = weak axis moment of inertia for pile ($ft^4$)
$E_s$ = soil modulus for clays = 0.465 $S_u$ (ksi)
$S_u$ = undrained shear strength of clays (ksf)
$n_h$ = rate of increase of soil modulus with depth for sands as specified in Table C10.4.6.3-2 (ksi/ft)

This procedure is taken from Davisson and Robinson (1965).

In Eqs. C10.7.3.13.4-1 and C10.7.3.13.4-2, the loading condition has been assumed to be axial load only, and the piles are assumed to be fixed at their ends. Because the equations give depth to fixity from the ground line, the Engineer must determine the boundary conditions at the top of the pile to determine the total unbraced length of the pile. If other loading or pile tip conditions exist, see Davisson and Robinson (1965).

The effect of pile spacing on the soil modulus has been studied by Prakash and Sharma (1990), who found that, at pile spacings greater than 8 times the pile width, neighboring piles have no effect on the soil modulus or buckling resistance. However, at a pile spacing of three times the pile width, the effective soil modulus is reduced to 25 percent of the value applicable to a single pile. For intermediate spacings, modulus values may be estimated by interpolation.

**10.7.4—Extreme Event Limit State**

The provisions of Article 10.5.5.3 shall apply.

For the applicable factored loads, including those specified in Article 10.7.1.6, for each extreme event limit state, the pile foundations shall be designed to have adequate factored axial and lateral resistance. For seismic design, all soil within and above the liquefiable zone, if the soil is liquefiable, shall not be considered to contribute bearing resistance. Downdrag resulting from liquefaction induced settlement shall be determined as specified in Article 3.11.8 and included in the loads applied to the foundation. Static downdrag loads should not be combined with seismic downdrag loads due to liquefaction.

The pile foundation shall also be designed to resist the horizontal force resulting from lateral spreading, if applicable, or the liquefiable soil shall be improved to prevent liquefaction and lateral spreading. For lateral soil resistance of the pile foundation, the *P-y* curve soil parameters should be reduced to account for liquefaction. To determine the amount of reduction, the duration of strong shaking and the ability of the soil to fully develop a liquefied condition during the period of strong shaking should be considered.

When designing for scour, the pile foundation design shall be conducted as described in Article 10.7.3.6, except that the check flood and resistance factors consistent with Article 10.5.5.3.2 shall be used.

**C10.7.4**

See Article C10.5.5.3.3.

### 10.7.5—Corrosion and Deterioration

The effects of corrosion and deterioration from environmental conditions shall be considered in the selection of the pile type and in the determination of the required pile cross-section.

As a minimum, the following types of deterioration shall be considered:

- corrosion of steel pile foundations, particularly in fill soils, low ph soils, and marine environments;
- sulfate, chloride, and acid attack of concrete pile foundations; and
- decay of timber piles from wetting and drying cycles or from insects or marine borers.

The following soil or site conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- resistivity less than 2,000 ohm-cm,
- pH less than 5.5,
- pH between 5.5 and 8.5 in soils with high organic content,
- sulfate concentrations greater than 1,000 ppm,
- landfills and cinder fills,
- soils subject to mine or industrial drainage,
- areas with a mixture of high resistivity soils and low resistivity high alkaline soils, and
- insects (wood piles).

The following water conditions should be considered as indicative of a potential pile deterioration or corrosion situation:

- chloride content greater than 500 ppm,
- sulfate concentration greater than 500 ppm,
- mine or industrial runoff,
- high organic content,
- pH less than 5.5,
- marine borers, and
- piles exposed to wet/dry cycles.

When chemical wastes are suspected, a full chemical analysis of soil and groundwater samples shall be considered.

### C10.7.5

Resistivity, pH, chloride content, and sulfate concentration values have been adapted from those in Fang (1991) and Tomlinson (1987).

Some states use a coal tar epoxy paint system as a protective coating with good results.

The criterion for determining the potential for deterioration varies widely. An alternative set of recommendations is given by Elias (1990).

A field electrical resistivity survey or resistivity testing and pH testing of soil and groundwater samples may be used to evaluate the corrosion potential.

The deterioration potential of steel piles may be reduced by several methods, including protective coatings, concrete encasement, cathodic protection, use of special steel alloys, or increased steel area. Protective coatings should be resistant to abrasion and have a proven service record in the corrosive environment identified. Protective coatings should extend into noncorrosive soils a few feet because the lower portion of the coating is more susceptible to abrasion loss during installation.

Concrete encasement through the corrosive zone may also be used. The concrete mix should be of low permeability and placed properly. Steel piles protected by concrete encasement should be coated with a dielectric coating near the base of the concrete jacket.

The use of special steel alloys of nickel, copper, and potassium may also be used for increased corrosion resistance in the atmosphere or splash zone of marine piling.

Sacrificial steel area may also be used for corrosion resistance. This technique over sizes the steel section so that the available section after corrosion meets structural requirements.

Deterioration of concrete piles can be reduced by design procedures. These include use of a dense impermeable concrete, sulfate resisting Portland cement, increased steel cover, air-entrainment, reduced chloride content in the concrete mix, cathodic protection, and epoxy-coated reinforcement. Piles that are continuously submerged are less subject to deterioration. ACI 318, Section 4.5.2, provides maximum water-cement ratio requirements for special exposure conditions. ACI 318, Section 4.5.3, lists the appropriate types of cement for various types of sulfate exposure.

For prestressed concrete, ACI 318 recommends a maximum water-soluble chloride ion of 0.06 percent by weight of cement.

Cathodic protection of reinforcing and prestressing steel may be used to protect concrete from corrosion effects. This process induces electric flow from the anode to the cathode of the pile and reduces corrosion. An external DC power source may be required to drive the current. However, cathodic protection requires electrical continuity between all steel and that necessitates bonding the steel for electric connection. This bonding is expensive and usually precludes the use of cathodic protection of concrete piles.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Epoxy coating of pile reinforcement has been found in some cases to be useful in resisting corrosion. It is important to ensure that the coating is continuous and free of holidays.

More detail on design for corrosion or other forms of deterioration is contained in Hannigan et al. (2006).

### 10.7.6—Determination of Minimum Pile Penetration

The minimum pile penetration, if required for the particular site conditions and loading, shall be based on the maximum depth (i.e., tip elevation) needed to meet the following requirements as applicable:

- single and pile group settlement (service limit state)
- lateral deflection (service limit state)
- uplift (strength limit state)
- penetration into bearing soils needed to get below soil causing downdrag loads on the pile foundation resulting from static consolidation stresses on soft soil or downdrag loads due to liquefaction (strength and extreme event limit state, respectively)
- penetration into bearing soils needed to get below soil subject to scour
- penetration into bearing soils necessary to obtain fixity for resisting the applied lateral loads to the foundation (strength limit state)
- axial uplift, and nominal lateral resistance to resist extreme event limit state loads

The contract documents should indicate the minimum pile penetration, if applicable, as determined above only if one or more of the requirements listed above are applicable to the pile foundation. The contract documents should also include the required nominal axial compressive resistance, $R_{ndr}$ as specified in Article 10.7.7 and the method by which this resistance will be verified, if applicable, such that the resistance factor(s) used for design are consistent with the construction field verification methods of nominal axial compressive pile resistance.

### C10.7.6

A minimum pile penetration should only be specified if necessary to ensure that all of the applicable limit states are met. A minimum pile penetration should not be specified solely to meet axial compression resistance, i.e., bearing, unless field verification of the pile nominal bearing resistance is not performed as described in Article 10.7.3.8.

### 10.7.7—Determination of $R_{ndr}$ Used to Establish Contract Driving Criteria for Nominal Bearing Resistance

The value of $R_{ndr}$ used for the construction of the pile foundation to establish the driving criteria to obtain the nominal bearing resistance shall be the value that meets or exceeds the following limit states, as applicable:

- strength limit state nominal bearing resistance specified in Article 10.7.3.8
- strength limit state nominal bearing resistance, including downdrag specified in Article 10.7.3.7
- strength limit state nominal bearing resistance, accounting for scour specified in Article 10.7.3.6
- extreme event limit state nominal bearing resistance for seismic specified in Article 10.7.4

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- extreme event limit state nominal bearing resistance for scour specified in Article 10.7.4

**10.7.8—Drivability Analysis**

The establishment of the installation criteria for driven piles should include a drivability analysis. Except as specified herein, the drivability analysis shall be performed by the Engineer using a wave equation analysis, and the driving stresses ($\sigma_{dr}$) anywhere in the pile determined from the analysis shall be less than the following limits:

Steel piles, compression and tension:

$$\sigma_{dr} = 0.9\varphi_{da} f_y \quad (10.7.8\text{-}1)$$

where:

$f_y$ = specified minimum yield strength of the steel (ksi)
$\varphi_{da}$ = resistance factor as specified in Table 10.5.5.2.3-1

Concrete piles:

- In compression:

$$\sigma_{dr} = \varphi_{da} 0.85 f'_c \quad (10.7.8\text{-}2)$$

- In tension, considering only the steel reinforcement:

$$\sigma_{dr} = 0.7\varphi_{da} f_y \quad (10.7.8\text{-}3)$$

where:

$f'_c$ = compressive strength of the concrete (ksi)
$f_y$ = specified minimum yield strength of the steel reinforcement (ksi)

Prestressed concrete piles, normal environments:

- In compression:

$$\sigma_{dr} = \varphi_{da} \left(0.85 f'_c - f_{pe}\right) \quad (10.7.8\text{-}4)$$

- In tension:

$$\sigma_{dr} = \varphi_{da} \left(0.095\sqrt{f'_c} + f_{pe}\right) \quad (10.7.8\text{-}5)$$

where:

$f_{pe}$ = effective prestressing stress in concrete (ksi)

Prestressed concrete piles, severe corrosive environments:

- In tension:

**C10.7.8**

Wave equation analyses should be conducted during design using a range of likely hammer/pile combinations, considering the soil and installation conditions at the foundation site. See Article 10.7.3.8.4 for additional considerations for conducting wave equation analyses. These analyses should be used to assess feasibility of the proposed foundation system and to establish installation criteria with regard to driving stresses to limit driving stresses to acceptable levels. For routine pile installation applications, e.g., smaller diameter, low nominal resistance piles, the development of installation criteria with regard to the limitation of driving stresses, e.g., minimum or maximum ram weight, hammer size, maximum acceptable driving resistance, etc., may be based on local experience, rather than conducting a detailed wave equation analysis that is project specific. Local experience could include previous drivability analysis results and actual pile driving experience that are applicable to the project specific situation at hand. Otherwise, a project specific drivability study should be conducted.

Drivability analyses may also be conducted as part of the project construction phase. When conducted during the construction phase, the drivability analysis shall be conducted using the contractor's proposed driving system. This information should be supplied by the contractor. This drivability analysis should be used to determine if the contractor's proposed driving system is capable of driving the pile to the maximum resistance anticipated without exceeding the factored structural resistance available, i.e., $\sigma_{dr}$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$\sigma_{dr} = \varphi_{da} f_{pe} \quad (10.7.8\text{-}6)$$

Timber piles, in compression and tension:

$$\sigma_{dr} = \varphi_{da}(2.6F_{co}) \quad (10.7.8\text{-}7)$$

where:

$F_{co}$ = base resistance of wood in compression parallel to the grain as specified in Article 8.4.1.3 (ksi)

This drivability analysis shall be based on the maximum driving resistance needed:

- to obtain minimum penetration requirements specified in Article 10.7.6,
- to overcome resistance of soil that cannot be counted upon to provide axial or lateral resistance throughout the design life of the structure, e.g., material subject to scour, or material subject to downdrag, and
- to obtain the required nominal bearing resistance.

In addition to this drivability analysis, the best approach to controlling driving stresses during pile installation is to conduct dynamic testing with signal matching to verify the accuracy of the wave equation analysis results. Note that if a drivability analysis is conducted using the wave equation for acceptance of the contractor's proposed driving system, but a different method is used to develop driving resistance, i.e., blow count, criterion to obtain the specified nominal pile resistance, e.g., a driving formula, the difference in the methods regarding the predicted driving resistance should be taken into account when evaluating the contractor's driving system. For example, the wave equation analysis could indicate that the contractor's hammer can achieve the desired bearing resistance, but the driving formula could indicate the driving resistance at the required nominal bearing is too high. Such differences should be considered when setting up the driving system acceptance requirements in the contract documents, though it is preferable to be consistent in the method used for acceptance of the contractor's driving system and the one used for developing driving criteria.

The selection of a blow count limit as a definition of refusal is difficult because it can depend on the site soil profile, the pile type, hammer performance, and possibly hammer manufacturer limitations to prevent hammer damage. In general, blow counts greater than 10–15 blows per inch should be used with care, particularly with concrete or timber piles. In cases where the driving is easy until near the end of driving, a higher blow count may sometimes be satisfactory, but if a high blow count is required over a large percentage of the depth, even ten blows per inch may be too large.

### 10.7.9—Probe Piles

Probe piles should be driven at several locations on the site to establish order length. If dynamic measurements are not taken, these probe piles should be driven after the driving criteria have been established.

If dynamic measurements during driving are taken, both order lengths and driving criteria should be established after the probe pile(s) are driven.

### C10.7.9

Probe piles are sometimes known as test piles or indicator piles. It is common practice to drive probe piles at the beginning of the project (particularly with concrete piles) to establish pile order lengths and/or to evaluate site variability whether or not dynamic measurements are taken.

## 10.8—DRILLED SHAFTS

### 10.8.1—General

#### 10.8.1.1—Scope

The provisions of this Section shall apply to the design of drilled shafts. Throughout these provisions, the use of the term "drilled shaft" shall be interpreted to mean a shaft constructed using either drilling (open hole or with drilling slurry) or casing plus excavation equipment and technology.

These provisions shall also apply to shafts that are constructed using casing advancers that twist or rotate

#### C10.8.1.1

Drilled shafts may be an economical alternative to spread footing or pile foundations, particularly when spread footings cannot be founded on suitable soil or rock strata within a reasonable depth or when driven piles are not viable. Drilled shafts may be an economical alternative to spread footings where scour depth is large. Drilled shafts may also be considered to resist high lateral or axial loads, or when deformation tolerances are small.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

casings into the ground concurrent with excavation rather than drilling.

The provisions of this Section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

For example, a movable bridge is a bridge where it is desirable to keep deformations small.

Drilled shafts are classified according to their primary mechanism for deriving load resistance either as floating (friction) shafts, i.e., shafts transferring load primarily by side resistance, or end-bearing shafts, i.e., shafts transferring load primarily by tip resistance.

It is recommended that the shaft design be reviewed for constructability prior to advertising the project for bids.

### 10.8.1.2—Shaft Spacing, Clearance, and Embedment into Cap

### C10.8.1.2

If the center-to-center spacing of drilled shafts is less than 4.0 diameters, the interaction effects between adjacent shafts shall be evaluated. If the center-to-center spacing of drilled shafts is less than 6.0 diameters, the sequence of construction should be specified in the contract documents.

Shafts used in groups should be located such that the distance from the side of any shaft to the nearest edge of the cap is not less than 12.0 in. Shafts shall be embedded sufficiently into the cap to develop the required structural resistance.

Larger spacing may be required to preserve shaft excavation stability or to prevent communication between shafts during excavation and concrete placement.

Shaft spacing may be decreased if casing construction methods are required to maintain excavation stability and to prevent interaction between adjacent shafts.

### 10.8.1.3—Shaft Diameter and Enlarged Bases

### C10.8.1.3

If the shaft is to be manually inspected, the shaft diameter should not be less than 30.0 in. The diameter of columns supported by shafts should be smaller than or equal to the diameter of the drilled shaft.

Nominal shaft diameters used for both geotechnical and structural design of shafts should be selected based on available diameter sizes.

If the shaft and the column are the same diameter, it should be recognized that the placement tolerance of drilled shafts is such that it will likely affect the column location. The shaft and column diameter should be determined based on the shaft placement tolerance, column and shaft reinforcing clearances, and the constructability of placing the column reinforcing in the shaft. A horizontal construction joint in the shaft at the bottom of the column reinforcing will facilitate constructability. Making allowance for the tolerance where the column connects with the superstructure, which could affect column alignment, can also accommodate this shaft construction tolerance.

In drilling rock sockets, it is common to use casing through the soil zone to temporarily support the soil to prevent cave-in, allow inspection and to produce a seal along the soil-rock contact to minimize infiltration of groundwater into the socket. Depending on the method of excavation, the diameter of the rock socket may need to be sized at least 6.0 in. smaller than the nominal casing size to permit seating of casing and insertion of rock drilling equipment.

In stiff cohesive soils, an enlarged base (bell, or underream) may be used at the shaft tip to increase the tip bearing area to reduce the unit end bearing pressure or to provide additional resistance to uplift loads.

Where practical, consideration should be given to extension of the shaft to a greater depth to avoid the difficulty and expense of excavation for enlarged bases.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Where the bottom of the drilled hole is dry, cleaned and inspected prior to concrete placement, the entire base area may be taken as effective in transferring load.

### 10.8.1.4—Battered Shafts

Battered shafts should be avoided. Where increased lateral resistance is needed, consideration should be given to increasing the shaft diameter or increasing the number of shafts.

### C10.8.1.4

Due to problems associated with hole stability during excavation, installation, and with removal of casing during installation of the rebar cage and concrete placement, construction of battered shafts is very difficult.

### 10.8.1.5—Drilled Shaft Resistance

Drilled shafts shall be designed to have adequate axial and structural resistances, tolerable settlements, and tolerable lateral displacements.

The axial resistance of drilled shafts shall be determined through a suitable combination of subsurface investigations, laboratory and/or in-situ tests, analytical methods, and load tests, with reference to the history of past performance. Consideration shall also be given to:

- the difference between the resistance of a single shaft and that of a group of shafts;
- the resistance of the underlying strata to support the load of the shaft group;
- the effects of constructing the shaft(s) on adjacent structures;
- the possibility of scour and its effect;
- the transmission of forces, such as downdrag forces, from consolidating soil;
- minimum shaft penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads and seismic conditions;
- satisfactory behavior under service loads;
- drilled shaft nominal structural resistance; and
- long-term durability of the shaft in service, i.e., corrosion and deterioration.

Resistance factors for shaft axial resistance for the strength limit state shall be as specified in Table 10.5.5.2.4-1.

The method of construction may affect the shaft axial and lateral resistance. The shaft design parameters shall take into account the likely construction methodologies used to install the shaft.

### C10.8.1.5

The drilled shaft design process is discussed in detail in Drilled Shafts: Construction Procedures and Design Methods (Brown et al., 2010).

The performance of drilled shaft foundations can be greatly affected by the method of construction, particularly side resistance. The Designer should consider the effects of ground and groundwater conditions on shaft construction operations and delineate, where necessary, the general method of construction to be followed to ensure the expected performance. Because shafts derive their resistance from side and tip resistance, which is a function of the condition of the materials in direct contact with the shaft, it is important that the construction procedures be consistent with the material conditions assumed in the design. Softening, loosening, or other changes in soil and rock conditions caused by the construction method could result in a reduction in shaft resistance and an increase in shaft displacement. Therefore, evaluation of the effects of the shaft construction procedure on resistance should be considered an inherent aspect of the design. Use of slurries, varying shaft diameters, and post grouting can also affect shaft resistance.

Soil parameters should be varied systematically to model the range of anticipated conditions. Both vertical and lateral resistance should be evaluated in this manner.

Procedures that may affect axial or lateral shaft resistance include, but are not limited to, the following:

- Artificial socket roughening, if included in the design nominal axial resistance assumptions.
- Removal of temporary casing where the design is dependent on concrete-to-soil adhesion.
- The use of permanent casing.
- Use of tooling that produces a uniform cross-section where the design of the shaft to resist lateral loads cannot tolerate the change in stiffness if telescoped casing is used.

It should be recognized that the design procedures provided in these Specifications assume compliance to construction specifications that will produce a high-quality shaft. Performance criteria should be included in the construction specifications that require:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- shaft bottom cleanout criteria,
- appropriate means to prevent side wall movement or failure (caving) such as temporary casing, slurry, or a combination of the two,
- slurry maintenance requirements including minimum slurry head requirements, slurry testing requirements, and maximum time the shaft may be left open before concrete placement.

If for some reason one or more of these performance criteria are not met, the design should be reevaluated and the shaft repaired or replaced as necessary.

### 10.8.1.6—Determination of Shaft Loads

*10.8.1.6.1—General*

*C10.8.1.6.1*

The factored loads to be used in shaft foundation design shall be as specified in Section 3. Computational assumptions that shall be used in determining individual shaft loads are also specified in Section 3.

The specification and determination of top of cap loads is discussed extensively in Section 3. It should be noted that Article 3.6.2.1 states that dynamic load allowance need not be applied to foundation elements that are below the ground surface. Therefore, if shafts extend above the ground surface to act as columns the dynamic load allowance should be included in evaluating the structural resistance of that part of the shaft above the ground surface. The dynamic load allowance may be ignored in evaluating the geotechnical resistance.

*10.8.1.6.2—Downdrag*

*C10.8.1.6.2*

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply for determination of load due to downdrag.

For shafts with tip bearing in a dense stratum or rock where design of the shaft is structurally controlled, downdrag shall be considered at the strength and extreme event limit states.

For shafts with tip bearing in soil, downdrag shall not be considered at the strength and extreme limit states if settlement of the shaft is less than failure criterion.

See Article C3.11.8.

Downdrag loads may be estimated using the α-method, as specified in Article 10.8.3.5.1b, to calculate negative shaft friction. As with positive shaft resistance, shaft length assumed to not contribute to nominal side resistance should also be assumed to not contribute to downdrag loads.

When using the α-method, an allowance should be made for a possible increase in the undrained shear strength as consolidation occurs. Downdrag loads may also come from cohesionless soils above settling cohesive soils. The downdrag caused by settling cohesionless soils may be estimated using the β method presented in Article 10.8.3.5.2.

Downdrag occurs in response to relative downward deformation of the surrounding soil to that of the shaft, and may not exist if downward movement of the drilled shaft in response to axial compression forces exceeds the vertical deformation of the soil. The response of a drilled shaft to downdrag in combination with the other forces acting at the head of the shaft therefore is complex and a realistic evaluation of actual limit states that may occur requires careful consideration of two issues: (1) drilled shaft load-settlement behavior and (2) the time period over which downdrag occurs relative to the time period over which nonpermanent components of load occur. When these factors are taken into account, it is appropriate to consider different downdrag forces for evaluation of geotechnical strength limit states than for

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

structural strength limit states. These issues are addressed in Brown et al. (2010).

*10.8.1.6.3—Uplift*

*C10.8.1.6.3*

The provisions in Article 10.7.1.6.3 shall apply.

See Article C10.7.1.6.3.

## 10.8.2—Service Limit State Design

### 10.8.2.1—Tolerable Movements

**C10.8.2.1**

The requirements of Article 10.5.2.1 shall apply.

See Article C10.5.2.1.

### 10.8.2.2—Settlement

*10.8.2.2.1—General*

The settlement of a drilled shaft foundation involving either single-drilled shafts or groups of drilled shafts shall not exceed the movement criteria selected in accordance with Article 10.5.2.1.

*10.8.2.2.2—Settlement of Single-Drilled Shaft*

*C10.8.2.2.2*

The settlement of single-drilled shafts shall be estimated as a sum of the following:

- short-term settlement resulting from load transfer,
- consolidation settlement if constructed where cohesive soil exhist beneath the shaft tip, and
- axial compression of the shaft.

The normalized load-settlement curves shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4 should be used to limit the nominal shaft axial resistance computed as specified for the strength limit state in Article 10.8.3 for service limit state tolerable movements. Consistent values of normalized settlement shall be used for limiting the base and side resistance when using these Figures. Long-term settlement should be computed according to Article 10.7.2 using the equivalent footing method and added to the short-term settlements estimated using Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

O'Neill and Reese (1999) have summarized load-settlement data for drilled shafts in dimensionless form, as shown in Figures 10.8.2.2.2-1 through 10.8.2.2.2-4. These curves do not include consideration of long-term consolidation settlement for shafts in cohesive soils. Figures 10.8.2.2.2-1 and 10.8.2.2.2-2 show the load-settlement curves in side resistance and in end bearing for shafts in cohesive soils. Figures 10.8.2.2.2-3 and 10.8.2.2.2-4 are similar curves for shafts in cohesionless soils. These curves should be used for estimating short-term settlements of drilled shafts.

The designer should exercise judgment relative to whether the trend line, one of the limits, or some relation in between should be used from Figures 10.8.2.2.2-1 through 10.8.2.2.2-4.

The values of the load-settlement curves in side resistance were obtained at different depths, taking into account elastic shortening of the shaft. Although elastic shortening may be small in relatively short shafts, it may be substantial in longer shafts. The amount of elastic shortening in drilled shafts varies with depth. O'Neill and Reese (1999) have described an approximate procedure for estimating the elastic shortening of long- drilled shafts.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

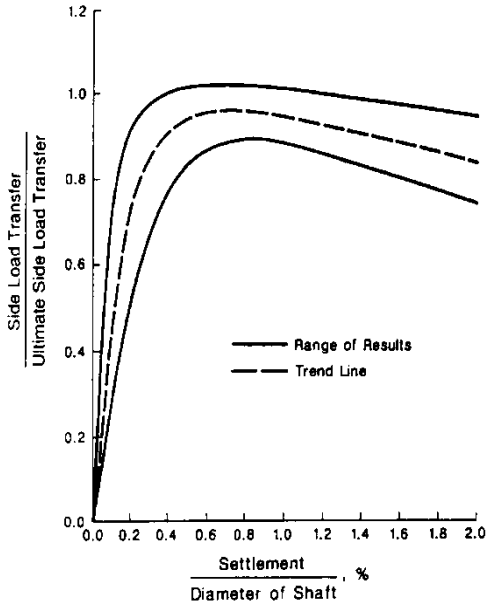

**Figure 10.8.2.2.2-1 Normalized Load Transfer in Side Resistance versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)**

Induced setttlements for isolated drilled shafts are different for elements in cohesive soils and in cohesionless soils. In cohesive soils, the failure threshold, or nominal axial resistance corresponds to mobilization of the full available side resistance, plus the full available base resistance. In cohesive soils, the failure threshold has been shown to occur at an average normalized deformation of four percent of the shaft diameter. In cohesionless soils, the failure threshold is the force corresponding to mobilization of the full side resistance plus the base resistance, corresponding to settlement at a defined failure criterion. This has been traditionally defined as the bearing pressure required to cause vertical deformation equal to five percent of the shaft diameter, even though this does not correspond to complete failure of the soil beneath the base of the shaft.

Note that nominal base resistance in cohesionless soils is calculated according to the empirical correlation given by Eq. 10.8.3.5.2c-1 in terms of *N*-value. That relationship was developed using a base resistance corresponding to five percent normalized displacement. If a normalized displacement other than five percent is used, the base resistance calculated by Eq. 10.8.3.5.2c-1 must be corrected.

The curves in Figures 10.8.2.2.2-1 and 10.8.2.2.2-3 also show the settlements at which the side resistance is mobilized. The shaft skin friction, $R_s$, is typically fully mobilized at displacements of 0.2 percent to 0.8 percent of the shaft diameter for shafts in cohesive soils. For shafts in cohesionless soils, this value is 0.1 percent to 1.0 percent.

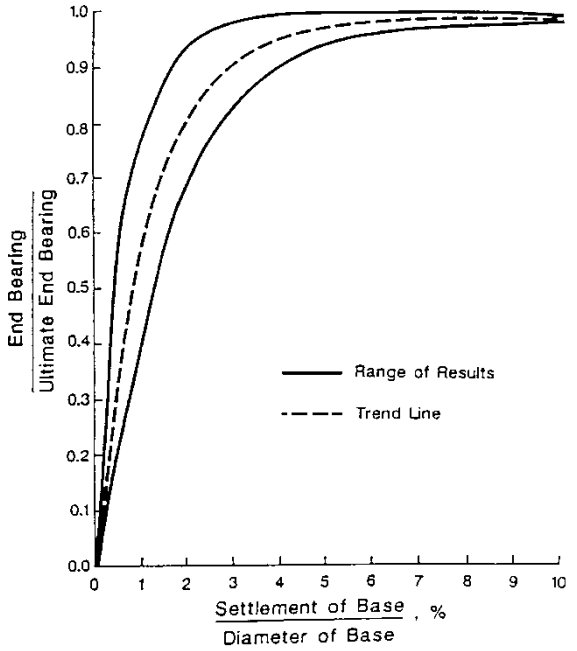

**Figure 10.8.2.2.2-2—Normalized Load Transfer in End Bearing versus Settlement in Cohesive Soils (from O'Neill and Reese, 1999)**

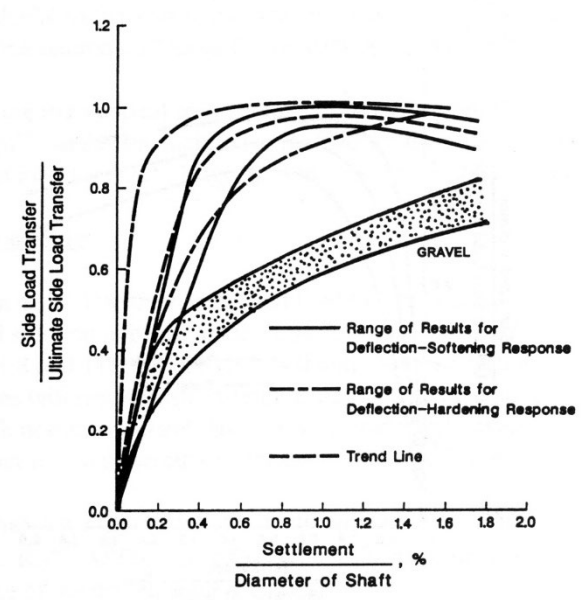

**Figure 10.8.2.2.2-3—Normalized Load Transfer in Side Resistance versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)**

The deflection-softening response typically applies to cemented or partially-cemented soils, or other soils that exhibit brittle behavior, which have low residual shear strengths at larger deformations. Note that the trend line for sands is a reasonable approximation for either the deflection-softening or deflection-hardening response.

The normalized load-settlement curves require separate evaluation of an isolated drilled shaft for side and base resistance. Brown et al. (2010) provide alternate normalized load-settlement curves that may be used for estimation of settlement of a single drilled shaft considering combined side and base resistance. The method is based on modeling the average load deformation behavior observed from field load tests and incorporates the load test data used in development of the curves provided by O'Neill and Reese (1999). Additional methods that consider numerical simulations of axial load transfer and approximations based on elasto-plastic solutions are available in Brown et al. (2010).

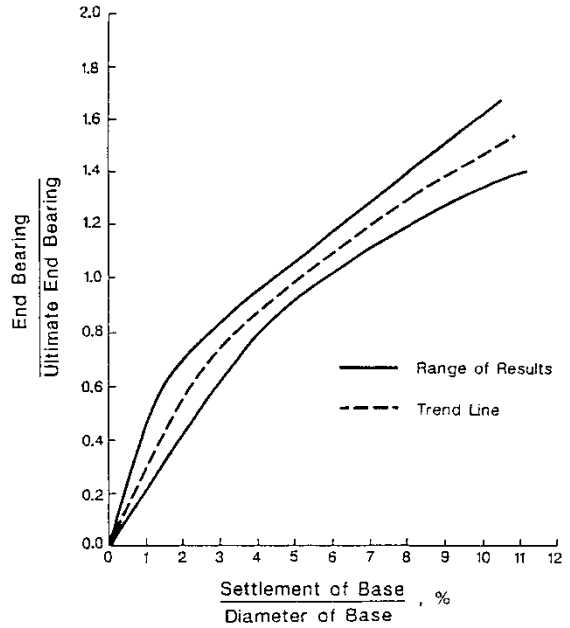

**Figure 10.8.2.2.2-4—Normalized Load Transfer in End Bearing versus Settlement in Cohesionless Soils (from O'Neill and Reese, 1999)**

*10.8.2.2.3—Intermediate Geo Materials (IGMs)*

For detailed settlement estimation of shafts in IGMs, the procedures described by Brown et al. (2010) should be used.

*C10.8.2.2.3*

IGMs are defined by Brown et al. (2010) as follows:

- *Cohesive IGM*—clay shales or mudstones with an $S_u$ of 5 to 50 ksf

*10.8.2.2.4—Group Settlement*

The provisions of Article 10.7.2.3 shall apply. Shaft group effect shall be considered for groups of two shafts or more.

*C10.8.2.2.4*

See Article C10.7.2.3.

O'Neill and Reese (1999) summarize various studies on the effects of shaft group behavior. These studies were for groups that consisted of 1 × 2 to 3 × 3 shafts. These studies suggest that group effects are relatively unimportant for shaft center-to-center spacing of 5*D* or greater.

### 10.8.2.3—Horizontal Movement of Shafts and Shaft Groups

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

For shafts socketed into rock, the input properties used to determine the response of the rock to lateral loading shall consider both the intact shear strength of the rock and the rock mass characteristics. The designer shall also consider the orientation and condition of discontinuities of the overall rock mass. Where specific adversely oriented discontinuities are not present but the rock mass is fractured such that its intact strength is considered compromised, the rock mass shear strength parameters should be assessed using the procedures for GSI rating in Article 10.4.6.4. For lateral deflection of the rock adjacent to the shaft greater than 0.0004*b*, where *b* is

### C10.8.2.3

See Articles C10.5.2.1 and C10.7.2.4.

For shafts socketed into rock, approaches to developing *P-y* response of rock masses include both a weak rock response and a strong rock response. For the strong rock response, the potential for brittle fracture should be considered. If horizontal deflection of the rock mass is greater than 0.0004*b*, a lateral load test to evaluate the response of the rock to lateral loading should be considered. Brown et al. (2010) provides a summary of a methodology that may be used to estimate the lateral load response of shafts in rock. Additional background on lateral loading of shafts in rock is provided in Turner (2006).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

the diameter of the rock socket, the potential for brittle fracture of the rock shall be considered.

These methods for estimating the response of shafts in rock subjected to lateral loading use the unconfined compressive strength of the intact rock as the main input property. While this property is meaningful for intact rock, and was the key parameter used to correlate to shaft lateral load response in rock, it is not meaningful for fractured rock masses. If the rock mass is fractured enough to justify characterizing the rock shear strength using the GSI, the rock mass should be characterized as a $c$-$\phi$ material, and confining stress (i.e., $\sigma'_3$) present within the rock mass should be considered when establishing a rock mass shear strength for lateral response of the shaft. If the *P-y* method of analysis is used to model horizontal resistance, user-specified *P-y* curves should be derived. A method for developing hyperbolic *P-y* curves isdescribed by Liang et al. (2009).

**10.8.2.4—Settlement Due to Downdrag**

**C10.8.2.4**

The provisions of Article 10.7.2.5 shall apply.

See Article C10.7.2.5.

**10.8.2.5—Lateral Squeeze**

**C10.8.2.5**

The provisions of Article 10.7.2.6 shall apply.

See Article C10.7.2.6.

**10.8.3—Strength Limit State Design**

**10.8.3.1—General**

The nominal shaft resistances that shall be considered at the strength limit state include:

- axial compression resistance,
- axial uplift resistance,
- punching of shafts through strong soil into a weaker layer,
- lateral geotechnical resistance of soil and rock stratum,
- resistance when scour occurs,
- axial resistance when downdrag occurs, and
- structural resistance of shafts.

**10.8.3.2—Groundwater Table and Buoyancy**

**C10.8.3.2**

The provisions of Article 10.7.3.5 shall apply.

See Article C10.7.3.5.

**10.8.3.3—Scour**

**C10.8.3.3**

The provisions of Article 10.7.3.6 shall apply.

See Article C10.7.3.6.

**10.8.3.4—Downdrag**

**C10.8.3.4**

The foundation should be designed so that the available factored axial geotechnical resistance is greater than the factored loads applied to the shaft, including the downdrag, at the strength limit state. The nominal shaft resistance available to support structure loads plus downdrag shall be estimated by considering only the

The static analysis procedures in Article 10.8.3.5 may be used to estimate the available drilled shaft nominal side and tip resistances to withstand the downdrag plus other axial force effects.

Nominal resistance may also be estimated using an instrumented static load test provided the side resistance

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

positive skin and tip resistance below the lowest layer contributing to the downdrag. The drilled shaft shall be designed structurally to resist the downdrag plus structure loads.

within the zone contributing to downdrag is subtracted from the resistance determined from the load test.

As stated in Article C10.8.1.6.2, it is appropriate to apply different downdrag forces for evaluation of geotechnical strength limit states than for structural strength limit states. A drilled shaft with its tip bearing in stiff material, such as rock or hard soil, would be expected to limit settlement to very small values. In this case, the full downdrag force could occur in combination with the other axial force effects because downdrag will not be reduced if there is little or no downward movement of the shaft. Therefore, the factored force effects resulting from all load components, including full factored downdrag, should be used to check the structural strength limit state of the drilled shaft.

A rational approach to evaluating this strength limit state will incorporate the force effects occurring at this magnitude of downward displacement. This will include the factored axial force effects transmitted to the head of the shaft plus the downdrag loads occurring at a downward displacement defining the failure criterion. In many cases, this amount of downward displacement will reduce or eliminate downdrag. For soil layers that undergo settlement exceeding the failure criterion (for example, five percent of $B$ for shafts bearing in sand), downdrag loads are likely to remain and should be included. This approach requires the designer to predict the magnitude of downdrag load occurring at a specified downward displacement. This can be accomplished using the hand calculation procedure described in Brown et al. (2010) or with commercially available software.

When downdrag loads are determined to exist at a downward displacement defining failure, evaluation of drilled shafts for the geotechnical strength limit state in compression should be conducted under a load combination that is limited to permanent loads only, including the calculated downdrag load at a settlement defining the failure criterion but excluding nonpermanent loads, such as live load, temperature changes, etc. See Brown et al. (2010) for further discussion.

When analysis of a shaft subjected to downdrag shows that the downdrag load would be eliminated in order to achieve a defined downward displacement, evaluation of geotechnical and structural strength limit states in compression should be conducted under the full-load combination corresponding to the relevant strength limit state, including the non-permanent components of load but not including downdrag.

### 10.8.3.5—Nominal Axial Compression Resistance of Single Drilled Shafts

The factored resistance of drilled shafts, $R_R$, shall be taken as:

$$R_R = \varphi R_n = \varphi_{qp} R_p + \varphi_{qs} R_s \qquad (10.8.3.5\text{-}1)$$

### C10.8.3.5

The nominal axial compression resistance of a shaft is derived from the tip resistance and/or shaft side resistance, i.e., skin friction. Both the tip and shaft resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement, as described in Article 10.8.2.2.2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

in which:

$$R_p = q_p A_p \quad (10.8.3.5\text{-}2)$$

$$R_S = q_S A_S \quad (10.8.3.5\text{-}3)$$

where:

$R_p$ = nominal shaft tip resistance (kips)
$R_s$ = nominal shaft side resistance (kips)
$\varphi_{qp}$ = resistance factor for tip resistance specified in Table 10.5.5.2.4-1
$\varphi_{qs}$ = resistance factor for shaft side resistance specified in Table 10.5.5.2.4-1
$q_p$ = unit tip resistance (ksf)
$q_s$ = unit side resistance (ksf)
$A_p$ = area of shaft tip ($ft^2$)
$A_s$ = area of shaft side surface ($ft^2$)

The methods for estimating drilled shaft resistance provided in this Article should be used. Shaft strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

*10.8.3.5.1—Estimation of Drilled Shaft Resistance in Cohesive Soils*

*10.8.3.5.1a—General*

Drilled shafts in cohesive soils should be designed by total and effective stress methods for undrained and drained loading conditions, respectively.

*10.8.3.5.1b—Side Resistance*

The nominal unit side resistance, $q_S$, in ksf, for shafts in cohesive soil loaded under undrained loading conditions by the α-Method shall be taken as:

$$q_s = \alpha S_u \quad (10.8.3.5.1b\text{-}1)$$

in which:

$$\alpha = 0.55 \text{ for } \frac{S_u}{p_a} \le 1.5 \quad (10.8.3.5.1b\text{-}2)$$

For consistency in the interpretation of both static load tests (see Article 10.8.3.5.6) and the normalized curves of Article 10.8.2.2.2, it is customary to establish the failure criterion at the strength limit state at a gross deflection equal to five percent of the base diameter for drilled shafts.

O'Neill and Reese (1999) identify several methods for estimating the resistance of drilled shafts in cohesive and granular soils, intermediate geomaterials, and rock. The most commonly used methods are provided in this Article. Methods other than the ones provided in detail in this Article may be used provided that adequate local or national experience with the specific method is available to have confidence that the method can be used successfully and that appropriate resistance factors can be determined. At present, it must be recognized that these resistance factors have been developed using a combination of calibration by fitting to previous allowable stress design (ASD) practice and reliability theory (see Allen, 2005 for additional details on the development of resistance factors for drilled shafts). Such methods may be used as an alternative to the specific methodology provided in this Article, provided that:

- the method selected consistently has been used with success on a regional or national basis.
- significant experience is available to demonstrate that success.
- as a minimum, calibration by fitting to allowable stress design is conducted to determine the appropriate resistance factor, if inadequate measured data are available to assess the alternative method using reliability theory. A similar approach as described by Allen (2005) should be used to select the resistance factor for the alternative method.

*C10.8.3.5.1b*

The α-method is based on total stress. For effective stress methods for shafts in clay, see Brown et al. (2010).

The adhesion factor is an empirical factor used to correlate the results of full-scale load tests with the material property or characteristic of the cohesive soil. The adhesion factor is usually related to $S_u$ and is derived from the results of full-scale pile and drilled shaft, load tests. Use of this approach presumes that the measured value of $S_u$ is correct and that all shaft behavior resulting from construction and loading can be lumped into a single

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$\alpha = 0.55 - 0.1\left(S_u / p_a - 1.5\right)$$
$$\text{for } 1.5 \le S_u / p_a \le 2.5 \qquad (10.8.3.5.1b\text{-}3)$$

where:

$S_u$ = undrained shear strength (ksf)
$\alpha$ = adhesion factor (dim)
$p_a$ = atmospheric pressure (= 2.12 ksf)

The following portions of a drilled shaft, illustrated in Figure 10.8.3.5.1b-1, should not be taken to contribute to the development of resistance through skin friction:

- at least the top 5.0 ft of any shaft; and
- periphery of belled ends, if used.

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

Values of $\alpha$ for contributing portions of shafts excavated dry in open or cased holes should be as specified in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3.

parameter. Neither presumption is strictly correct, but the approach is used due to its simplicity.

Steel casing will generally reduce the side resistance of a shaft. No specific data for drilled shafts in clay are available regarding the reduction in skin friction resulting from the use of permanent casing relative to concrete placed directly against the soil when the casing is vibrated or rotated into the soil. Interface shear resistance for steel against clay can vary from 50 to 80 percent of the interface shear resistance for poured in place concrete against clay, depending on whether the steel is clean or rusty, respectively (Potyondy, 1961). A reduction factor applied to the calculated shaft side resistance of 0.6 to 0.75 is commonly used to account for the presence of permanent steel casing. Greater reduction in the side resistance may be necessary when installation methods result in reduced contact between the ground and the casing.

If open-ended pipe piles are driven full depth with an impact hammer before soil inside the pile is removed, and left as a permanent casing, driven pile static analysis methods may be used to estimate the side resistance as described in Article 10.7.3.8.6.

The upper 5.0 ft of the shaft is ignored in estimating $R_n$, to account for the effects of seasonal moisture changes, disturbance during construction, cyclic lateral loading, and low lateral stresses from freshly placed concrete.

Bells or underreams constructed in stiff fissured clay often settle sufficiently to result in the formation of a gap above the bell that will eventually be filled by slumping soil. Slumping will tend to loosen the soil immediately above the bell and decrease the side resistance along the lower portion of the shaft.

The value of $\alpha$ is often considered to vary as a function of $S_u$. Values of $\alpha$ for drilled shafts are recommended as shown in Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3, based on the results of back-analyzed, full-scale load tests. The load tests were conducted in insensitive cohesive soils. Therefore, if shafts are constructed in sensitive clays, values of $\alpha$ may be different than those obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3. Other values of $\alpha$ may be used if based on the results of load tests.

The depth of 5.0 ft at the top of the shaft may need to be increased if the drilled shaft is installed in expansive clay, if scour deeper than 5.0 ft is anticipated, if there is substantial groundline deflection from lateral loading, or if there are other long-term loads or construction factors that could affect shaft resistance.

The values of $\alpha$ obtained from Eqs. 10.8.3.5.1b-2 and 10.8.3.5.1b-3 are considered applicable for both compression and uplift loading.

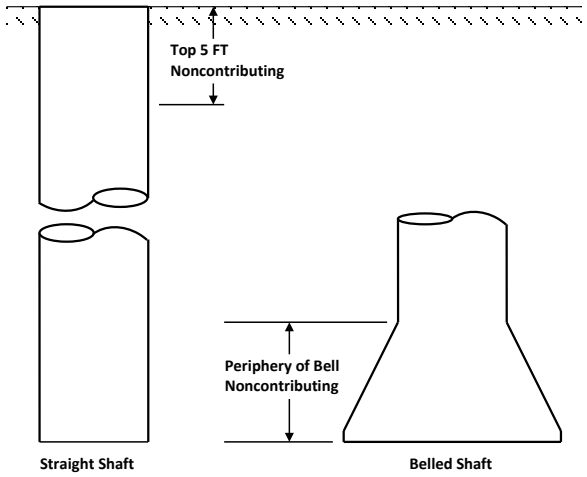

**Figure 10.8.3.5.1b-1—Explanation of Portions of Drilled Shafts Not Considered in Computing Side Resistance (Brown et al., 2010)**

*10.8.3.5.1c—Tip Resistance*

*C10.8.3.5.1c*

For axially loaded shafts in cohesive soil, the nominal unit tip resistance, $q_p$, by the total stress method as provided in Brown et al. (2010) shall be taken as:

$$q_p = N_c S_u \le 80.0 \text{ ksf} \qquad (10.8.3.5.1c\text{-}1)$$

in which:

$$N_c = 6\left[1 + 0.2\left(\frac{Z}{D}\right)\right] \le 9 \qquad (10.8.3.5.1c\text{-}2)$$

where:

$D$ = diameter of drilled shaft (ft)
$Z$ = penetration of shaft (ft)
$S_u$ = undrained shear strength (ksf)

The value of $S_u$ should be determined from the results of in-situ and/or laboratory testing of undisturbed samples obtained within a depth of 2.0 diameters below the tip of the shaft. If the soil within 2.0 diameters of the tip has $S_u$ <0.50 ksf, the value of $N_c$ should be multiplied by 0.67.

These equations are for total stress analysis. For effective stress methods for shafts in clay, see Brown et al. (2010).

The limiting value of 80.0 ksf for $q_p$ is not a theoretical limit but a limit based on the largest measured values. A higher limiting value may be used if based on the results of a load test, or previous successful experience in similar soils.

*10.8.3.5.2—Estimation of Drilled Shaft Resistance in Cohesionless Soils*

*10.8.3.5.2a—General*

*C10.8.3.5.2a*

Shafts in cohesionless soils should be designed by effective stress methods for drained loading conditions or by empirical methods based on in-situ test results.

The factored resistance should be determined in consideration of available experience with similar conditions.

The shear strength of cohesionless soils can be characterized by an angle of internal friction, $\phi_f$, or empirically related to its *SPT* blow count, *N*. Methods

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.8.3.5.2b—Side Resistance*

The side resistance for shafts in cohesionless soils shall be determined using the β method, take as:

$$q_s = \beta\, \sigma'_v \qquad (10.8.3.5.2b\text{-}1)$$

in which:

$$\beta = \left(1 - \sin\varphi'_f\right)\left(\frac{\sigma'_p}{\sigma'_v}\right)^{\sin\varphi'_f} \tan\varphi'_f \qquad (10.8.3.5.2b\text{-}2)$$

where:

β = load transfer coefficient (dim)
$\sigma'_f$ = friction angle of cohesionless soil layer (°)
$\sigma'_p$ = effective vertical preconsolidation stress
$\sigma'_v$ = vertical effective stress at soil layer mid-depth

The correlation for effective soil friction angle for use in the above equations shall be taken as:

$$\varphi'_f = 27.5 + 9.2\log\left[\left(N_1\right)_{60}\right] \qquad (10.8.3.5.2b\text{-}3)$$

where:

$(N_1)_{60}$ = *SPT N*-value corrected for effective overburden stress

The preconsolidation stress in Eq. 10.8.3.5.2b-2 should be approximated through correlation to *SPT N*-values. For sands:

$$\frac{\sigma'_p}{p_a} = 0.47\left(N_{60}\right)^m \qquad (10.8.3.5.2b\text{-}4)$$

where:

*m* = 0.6 for clean quartzitic sands
*m* = 0.8 for silty sand to sandy silts
$p_a$ = atmospheric pressure (same units as $\sigma'_p$ : 2.12 ksf or 14.7 psi)

For gravelly soils:

$$\frac{\sigma'_p}{p_a} = 0.15\left(N_{60}\right) \qquad (10.8.3.5.2b\text{-}5)$$

of estimating shaft resistance and end bearing are presented below. Judgment and experience should always be considered.

*C10.8.3.5.2b*

The method described herein is based on axial load tests on drilled shafts as presented by Chen and Kulhawy (2002) and updated by Kulhawy and Chen (2007). This method provides a rational approach for relating unit side resistance to N-values and to the state of effective stress acting at the soil-shaft interface. This approach replaces the previously used depth-dependent β-method developed by O'Neill and Reese (1999), which does not account for variations in *N*-value or effective stress on the calculated value of β. Further discussion, including the detailed development of Eq. 10.8.3.5.2b-2, is provided in (Brown et al., 2010).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

When permanent casing is used, the side resistance shall be adjusted with consideration to the type and length of casing to be used, and how it is installed.

Steel casing will generally reduce the side resistance of a shaft. No specific data for drilled shafts in cohesionless soil are available regarding the reduction in skin friction resulting from the use of permanent casing relative to concrete placed directly against the soil. Interface shear resistance for steel against cohesionless soil can vary from 50 to 80 percent of the interface shear resistance for poured in place concrete against cohesionless soil, depending on whether the steel is clean or rusty, respectively (Potyondy, 1961). Note that unit side resistance for poured in place concrete against cohesionless soil is nearly equal to the soil shear strength in most cases. A reduction factor applied to the calculated shaft side resistance of 0.6 to 0.75 is commonly used to account for the presence of permanent steel casing. Greater reduction in the side resistance may be necessary when installation methods result in reduced contact between the ground and the casing.

If open-ended pipe piles are driven full depth with an impact hammer before soil inside the pile is removed, and left as a permanent casing, driven pile static analysis methods may be used to estimate the side resistance as described in Article 10.7.3.8.6.

*10.8.3.5.2c—Tip Resistance*

*C10.8.3.5.2c*

The nominal tip resistance, $q_p$, in ksf, for drilled shafts in cohesionless soils by the method described in Brown et al. (2010) shall be taken as:

$$\text{If } N_{60} \le 50, \text{ then } q_p = 1.2N_{60} \qquad (10.8.3.5.2c\text{-}1)$$

where:

$N_{60}$ = average *SPT* blow count (corrected only for hammer efficiency) in the design zone under consideration (blows/ft)

The value of $q_p$ in Eq. 10.8.3.5.2c-1 should be limited to 60 ksf, unless greater values can be justified though load test data.

Brown et al. (2010) provide additional discussion regarding the computation of nominal tip resistance and on tip resistance in specific geologic environments.

*10.8.3.5.3—Shafts in Strong Soil Overlying Weaker Compressible Soil*

*C10.8.3.5.3*

Where a shaft is tipped in a strong soil layer overlying a weaker layer, the base resistance shall be reduced if the shaft base is within a distance of 1.5*B* of the top of the weaker layer. A weighted average should be used that varies linearly from the full base resistance in the overlying strong layer at a distance of 1.5*B* above the top of the weaker layer to the base resistance of the weaker layer at the top of the weaker layer.

The distance of 1.5*B* represents the zone of influence for general bearing capacity failure based on bearing capacity theory for deep foundations.

*10.8.3.5.4—Estimation of Drilled Shaft Resistance in Rock*

*10.8.3.5.4a—General*

Drilled shafts in rock subject to compressive loading shall be designed to support factored loads in:

- side-wall shear comprising skin friction on the wall of the rock socket; or
- end bearing on the material below the tip of the drilled shaft; or
- a combination of both.

The difference in the deformation required to mobilize skin friction in soil and rock versus what is required to mobilize end bearing shall be considered when estimating axial compressive resistance of shafts embedded in rock. Where end bearing in rock is used as part of the axial compressive resistance in the design, the contribution of skin friction in the rock shall be reduced to account for the loss of skin friction that occurs once the shear deformation along the shaft sides is greater than the peak rock shear deformation, i.e., once the rock shear strength begins to drop to a residual value.

*C10.8.3.5.4a*

Methods presented in this Article to calculate drilled shaft axial resistance require an estimate of the uniaxial compressive strength of rock core. Unless the rock is massive, the strength of the rock mass is most frequently controlled by the discontinuities, including orientation, length, and roughness, and the behavior of the material that may be present within the discontinuity, e.g., gouge or infilling. The methods presented are semi-empirical and are based on load test data and site-specific correlations between measured resistance and rock core strength.

Design based on side-wall shear alone should be considered for cases in which the base of the drilled hole cannot be cleaned and inspected or where it is determined that large movements of the shaft would be required to mobilize resistance in end bearing.

Design based on end-bearing alone should be considered where sound bedrock underlies low strength overburden materials, including highly weathered rock. In these cases, however, it may still be necessary to socket the shaft into rock to provide lateral stability.

Where the shaft is drilled some depth into sound rock, a combination of sidewall shear and end bearing can be assumed (Kulhawy and Goodman, 1980).

If the rock is degradable, use of special construction procedures, larger socket dimensions, or reduced socket resistance should be considered.

Factors that should be considered when making an engineering judgment to neglect any component of resistance (side or base) are discussed in Article 10.8.3.5.4d. In most cases, both side and base resistances should be included in limit state evaluation of rock-socketed shafts.

For drilled shafts installed in karstic formations, exploratory borings should be advanced at each drilled shaft location to identify potential cavities. Layers of compressible weak rock along the length of a rock socket and within approximately three socket diameters or more below the base of a drilled shaft may reduce the resistance of the shaft.

For rock that is stronger than concrete, the concrete shear strength will control the available side friction, and the strong rock will have a higher stiffness, allowing significant end bearing to be mobilized before the side wall shear strength reaches its peak value. Note that concrete typically reaches its peak shear strength at about 250 to 400 microstrain (for a 10-ft long rock socket, this is approximately 0.5 in. of deformation at the top of the rock socket). If strains or deformations greater than the value at the peak shear stress are anticipated to mobilize the desired end bearing in the rock, a residual value for the skin friction can still be used. Article 10.8.3.5.4d provides procedures for computing a residual value

*10.8.3.5.4b—Side Resistance*

For drilled shafts socketed into rock, unit side resistance, $q_s$ in ksf, shall be taken as (Kulhawy et al., 2005):

$$\frac{q_S}{p_a} = C\sqrt{\frac{q_u}{p_a}} \qquad (10.8.3.5.4b\text{-}1)$$

where:

$p_a$ = atmospheric pressure taken as 2.12 ksf
$C$ = regression coefficient taken as 1.0 for normal conditions
$q_u$ = uniaxial compressive strength of rock (ksf)

If the uniaxial compressive strength of rock forming the sidewall of the socket exceeds the drilled shaft concrete compressive strength, the value of concrete compressive strength ( $f_c'$ ) shall be substituted for $q_u$ in Eq. 10.8.3.5.4b-1.

For fractured rock that caves and cannot be drilled without some type of artificial support, the unit side resistance shall be taken as:

$$\frac{q_S}{p_a} = 0.65\alpha_E\sqrt{\frac{q_u}{p_a}} \qquad (10.8.3.5.4b\text{-}2)$$

The joint modification factor, $\alpha_E$ is given in Table 10.8.3.5.4b-1 based on RQD and visual inspection of joint surfaces.

**Table 10.8.3.5.4b-1—Estimation of $\alpha_E$ (O'Neill and Reese, 1999)**

| | Joint Modification Factor, $\alpha_E$ | |
|---|---|---|
| RDQ (%) | Closed Joints | Open or Gouge-Filled Joints |
| 100 | 1.00 | 0.85 |
| 70 | 0.85 | 0.55 |
| 50 | 0.60 | 0.55 |
| 30 | 0.50 | 0.50 |
| 20 | 0.45 | 0.45 |

of the skin friction based on the properties of the rock and shaft.

*C10.8.3.5.4b*

Eq. 10.8.3.5.4b-1 is based on regression analysis of load test data as reported by Kulhawy et al. (2005) and includes data from pervious studies by Horvath and Kenney (1979), Rowe and Armitage (1987), Kulhawy and Phoon (1993), and others. The recommended value of the regression coefficient $C$ = 1.0 is applicable to normal rock sockets, defined as sockets constructed with conventional equipment and resulting in nominally clean sidewalls without resorting to special procedures or artificial roughening. Rock that is prone to smearing or rapid deterioration upon exposure to atmospheric conditions, water, or slurry are outside the normal range and may require additional measures to insure reliable side resistance. Rocks exhibiting this type of behavior include clay shales and other argillaceous rocks. Rock that cannot support construction of an unsupported socket without caving is also outside the normal and will likely exhibit lower side resistance than given by Eq. 10.8.3.5.4b-1 with $C$ = 1.0. For additional guidance on assessing the magnitude of $C$, see Brown et al. (2010).

Shafts are sometimes constructed by supporting the hole with temporary casing or by grouting the rock ahead of the excavation. When using these construction methods, disturbance of the sidewall results in lower unit side resistances. Based on O'Neill and Reese (1999) and as discussed in Brown et al. (2010), the reduction in side resistance can be related empirically to the RQD and joint conditions.

*10.8.3.5.4c—Tip Resistance*

End-bearing for drilled shafts in rock may be taken as follows:

- If the rock below the base of the drilled shaft to a depth of 2.0*B* is either intact or tightly jointed, i.e., no compressible material or gouge-filled seams, and the depth of the socket is greater than 1.5*B*:

$$q_p = 2.5 q_u \qquad (10.8.3.5.4c\text{-}1)$$

- If the rock below the base of the shaft to a depth of 2.0*B* is jointed, the joints have random orientation, and the condition of the joints can be evaluated as:

$$q_p = A + q_u \left[ m_b \left( \frac{A}{q_u} \right) + s \right]^a \qquad (10.8.3.5.4c\text{-}2)$$

In which:

$$A = \sigma'_{vb} + q_u \left[ m_b \frac{\left(\sigma'_{v,b}\right)}{q_u} + s \right]^a \qquad (10.8.3.5.4c\text{-}3)$$

where:

$\sigma'_{vb}$ = vertical effective stress at the socket bearing elevation (tip elevation)

*s*, *a*, and $\imath_b$ = Hoek–Brown strength parameters for the fractured rock mass determined from GSI (see Article 10.4.6.4)

$q_u$ = uniaxial compressive strength of intact rock

Eq. 10.8.3.5.4c-1 should be used as an upper-bound limit to base resistance calculated by Eq. 10.8.2.5.4c-2, unless local experience or load tests can be used to validate higher values.

*C10.8.3.5.4c*

If end bearing in the rock is to be relied upon, and wet construction methods are used, bottom clean-out procedures such as airlifts should be specified to ensure removal of loose material before concrete placement.

The use of Eq. 10.8.3.5.4c-1 also requires that there are no solution cavities or voids below the base of the drilled shaft.

For further information, see Brown et al. (2010).

Bearing capacity theory provides a framework for evaluation of base resistance for cases where the bearing rock can be characterized by its GSI. Eq. 10.8.3.5.4c-2 (Turner and Ramey, 2010) is a lower bound solution for bearing resistance of a drilled shaft bearing on or socketed into a fractured rock mass. Fractured rock describes a rock mass intersected by multiple sets of intersecting joints such that the strength is controlled by the overall mass response and not by failure along pre-existing structural discontinuities. This generally applies to rock that can be characterized by the descriptive terms shown in Figure 10.4.6.4-1 (e.g., blocky, disintegrated, etc.).

*10.8.3.5.4d—Combined Side and Tip Resistance*

Design methods that consider the difference in shaft movement required to mobilize skin friction in rock versus what is required to mobilize end bearing shall be used to estimate axial compressive resistance of shafts embedded in rock.

*C10.8.3.5.4d*

A design decision to be addressed when using rock sockets is whether to neglect one or the other component of resistance (side or base). For example, design based on side resistance alone is sometimes assumed for cases in which the base of the drilled hole cannot be cleaned and inspected or where it is determined that large downward movement of the shaft would be required to mobilize tip resistance. However, before making a decision to omit tip resistance, careful consideration should be given to applying available methods of quality construction and inspection that can provide confidence in tip resistance. Quality construction practices can result in adequate clean-out at the base of rock sockets, including those constructed by wet methods. In many cases, the cost of quality control and assurance is offset by the economies

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

achieved in socket design by including tip resistance. Load testing provides a means to verify tip resistance in rock.

Reasons cited for neglecting side resistance of rock sockets include:

(1) the possibility of strain-softening behavior of the sidewall interface,
(2) the possibility of degradation of material at the borehole wall in argillaceous rocks, and
(3) uncertainty regarding the roughness of the sidewall.

Brittle behavior along the sidewall, in which side resistance exhibits a significant decrease beyond its peak value, is not commonly observed in load tests on rock sockets. If there is reason to believe strain softening will occur, laboratory direct shear tests of the rock-concrete interface can be used to evaluate the load-deformation behavior and account for it in design. These cases would also be strong candidates for conducting field load tests. Investigating the sidewall shear behavior through laboratory or field testing is generally more cost-effective than neglecting side resistance in the design. Application of quality control and assurance through inspection is also necessary to confirm that sidewall conditions in production shafts are of the same quality as laboratory or field test conditions.

Materials that are prone to degradation at the exposed surface of the borehole and are prone to a "smooth" sidewall generally are argillaceous sedimentary rocks such as shale, claystone, and siltstone. Degradation occurs due to expansion, opening of cracks and fissures combined with groundwater seepage, and by exposure to air and/or water used for drilling. Hassan and O'Neill (1997) note that this behavior is most prevalent in cohesive IGMs and that in the most severe cases degradation results in a smear zone at the interface. Smearing may reduce load transfer significantly. As reported by Abu-Hejleh et al. (2003), both smearing and smooth sidewall conditions can be prevented in cohesive IGMs by using roughening tools during the final pass with the rock auger or by grooving tools. Careful inspection prior to concrete placement is required to confirm roughness of the sidewalls. Only when these measures cannot be confirmed would there be cause for neglecting side resistance in design.

Analytical tools for evaluating the load transfer behavior of rock socketed shafts are given in Turner (2006) and Brown et al. (2010).

*10.8.3.5.5—Estimation of Drilled Shaft Resistance in Intermediate Geo Materials (IGMs)*

For detailed base and side resistance estimation procedures for shafts in cohesive IGMs, the procedures provided by Brown et al. (2010) should be used.

*C10.8.3.5.5*

See Article 10.8.2.2.3 for a definition of an IGM.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.8.3.5.6—Shaft Load Test*

When used, load tests shall be conducted in representative soil conditions using shafts constructed in a manner and of dimensions and materials similar to those planned for the production shafts. The load test shall follow the procedures specified in ASTM D1143. The loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used.

The nominal resistance shall be determined according to the failure definition of either:

- "plunging" of the drilled shaft, or
- a gross settlement or uplift of five percent of the diameter of the shaft if plunging does not occur.

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.4-1.

Regarding the use of shaft load test data to determine shaft resistance, the load test results should be applied to production shafts that are not load tested by matching the static resistance prediction to the load test results. The calibrated static analysis method should then be applied to adjacent locations within the site to determine the shaft tip elevation required, in consideration of variations in the geologic stratigraphy and design properties at each production shaft location. The definition of a site and number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.3.

*C10.8.3.5.6*

For a larger project where many shafts are to be used, it may be cost-effective to perform a full-scale load test on a drilled shaft during the design phase of a project to confirm response to load.

Load tests should be conducted following prescribed written procedures that have been developed from accepted standards and modified, as appropriate, for the conditions at the site. The Quick Test Procedure is desirable because it avoids problems that frequently arise when performing a static test that cannot be started and completed within an eight-hour period. Tests that extend over a longer period are difficult to perform due to the limited number of experienced personnel that are usually available. The Quick Test has proven to be easily performed in the field, and the results usually are satisfactory. However, if the formation in which the shaft is installed may be subject to significant creep settlement, alternative procedures provided in ASTM D1143 should be considered.

Load tests are conducted on full-scale drilled shaft foundations to provide data regarding nominal axial resistance, load-displacement response, and shaft performance under the design loads, and to permit assessment of the validity of the design assumptions for the soil conditions at the test shaft(s).

Tests can be conducted for compression, uplift, lateral loading, or for combinations of loading. Full-scale load tests in the field provide data that include the effects of soil, rock, and groundwater conditions at the site; the dimensions of the shaft; and the procedures used to construct the shaft.

The results of full-scale load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

For large diameter shafts, where conventional reaction frames become unmanageably large, load testing using Osterberg load cells may be considered. Additional discussion regarding load tests is provided in O'Neill and Reese (1999). Alternatively, smaller diameter shafts may be load tested to represent the larger diameter shafts (but no less than one-half the full scale production shaft diameter), provided that appropriate measures are taken to account for potential scale effects when extrapolating the results to the full scale production shafts.

Plunging occurs when a steady increase in movement results from incrementally small increases in load, e.g., 2.0 kips.

**10.8.3.6—Shaft Group Resistance**

*10.8.3.6.1—General*

Reduction in resistance from group effects shall be evaluated.

*C10.8.3.6.1*

If casing is advanced in front of the excavation heading, this reduction need not be made.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.8.3.6.2—Cohesive Soil*

The provisions of Article 10.7.3.9 shall apply.

The resistance factor for the group resistance of an equivalent pier or block failure provided in Table 10.5.5.2.4-1 shall apply where the cap is, or is not, in contact with the ground.

The resistance factors for the group resistance calculated using the sum of the individual drilled shaft resistances are the same as those for the single-drilled shaft resistances.

*C10.8.3.6.2*

The efficiency of groups of drilled shafts in cohesive soil may be less than that of the individual shaft due to the overlapping zones of shear deformation in the soil surrounding the shafts.

*10.8.3.6.3—Cohesionless Soil*

The individual nominal resistance of each shaft in a group should be reduced by applying an adjustment factor $\eta$ taken as shown in Table 10.8.3.6.3-1.

For intermediate spacings, the value of $\eta$ may be determined by linear interpolation.

*C10.8.3.6.3*

The bearing resistance of drilled shaft groups in sand is less than the sum of the individual shafts due to overlap of shear zones in the soil between adjacent shafts and loosening of the soil during construction. The recommended reduction factors are based in part on theoretical considerations and on limited load test results. See O'Neill and Reese (1999) for additional details and a summary of group load test results. It should be noted that most of the available group load test results were obtained for sands above the water table and for relatively small groups, e.g., groups of 3–9 shafts. For larger shaft groups or for shaft groups of any size below the water table, more conservative values of $\eta$ should be considered.

These reduction factors presume that good shaft installation practices are used to minimize or eliminate the relaxation of the soil between shafts and caving. If this cannot be adequately controlled due to difficult soil conditions or for other reasons, lower group reduction factors should be considered, or steps should be taken during and after shaft construction to restore the soil to its original condition.

**Table 10.8.3.6.3-1—Group Reduction Factors for Bearing Resistance of Shafts in Sand**

| Shaft Group Configuration | Shaft Center-to-Center Spacing | Special Conditions | Reduction Factor for Group Effects, $\eta$ |
|---|---|---|---|
| Single Row | 2*D* | | 0.90 |
| | 3*D* or more | | 1.0 |
| Multiple Row | 2.5*D* | | 0.67 |
| | 3*D* | | 0.80 |
| | 4*D* or more | | 1.0 |
| Single and Multiple Rows | 2*D* or more | Shaft group cap in intimate contact with ground consisting of medium dense or denser soil, and no scour below the shaft cap is anticipated | 1.0 |
| Single and Multiple Rows | 2*D* or more | Pressure grouting is used along the shaft sides to restore lateral stress losses caused by shaft installation, and the shaft tip is pressure grouted | 1.0 |

*10.8.3.6.4—Shaft Groups in Strong Soil Overlying Weak Soil*

For shaft groups that are collectively tipped within a strong soil layer overlying a soft, cohesive layer, block bearing resistance shall be evaluated in accordance with Article 10.7.3.9.

**10.8.3.7—Uplift Resistance**

*10.8.3.7.1—General*

Uplift resistance shall be evaluated when upward loads act on the drilled shafts. Drilled shafts subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

*10.8.3.7.2—Uplift Resistance of Single Drilled Shaft*

The uplift resistance of a single straight-sided drilled shaft should be estimated in a manner similar to that for determining side resistance for drilled shafts in compression, as specified in Article 10.8.3.5.

In determining the uplift resistance of a belled shaft, the side resistance above the bell should conservatively be neglected if the resistance of the bell is considered, and it can be assumed that the bell behaves as an anchor.

The factored nominal uplift resistance of a belled drilled shaft in a cohesive soil, $R_R$, in kips, should be determined as:

$$R_R = \varphi R_n = \varphi_{up} R_{sbell} \quad (10.8.3.7.2\text{-}1)$$

in which:

$$R_{s\ bell} = q_{s\ bell} A_u \quad (10.8.3.7.2\text{-}2)$$

where:

$q_{sbell}$ = $N_u S_u$ (ksf)
$A_u$ = $\pi(D_p^2 - D^2)/4$ (ft$^2$)
$N_u$ = uplift adhesion factor (dim)
$D_p$ = diameter of the bell (ft)
$D_b$ = depth of embedment in the founding layer (ft)
$D$ = shaft diameter (ft)
$S_u$ = undrained shear strength averaged over a distance of 2.0 bell diameters ($2D_p$) above the base (ksf)
$\varphi_{up}$ = resistance factor specified in Table 10.5.5.2.4-1

If the soil above the founding stratum is expansive, $S_u$ should be averaged over the lesser of either $2.0D_p$ above the bottom of the base or over the depth of penetration of the drilled shaft in the founding stratum.

*C10.8.3.7.2*

The resistance factors for uplift are lower than those for axial compression. One reason for this is that drilled shafts in tension unload the soil, thus reducing the overburden effective stress and hence the uplift side resistance of the drilled shaft. Empirical justification for uplift resistance factors is provided in Article C10.5.5.2.3 and in Allen (2005).

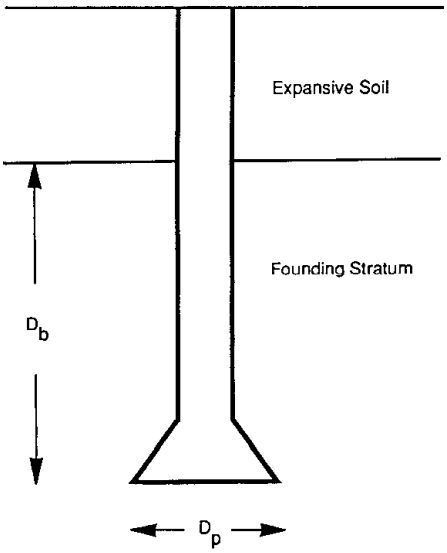

**Figure C10.8.3.7.2-1—Uplift of a Belled Drilled Shaft**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The value of $N_u$ may be assumed to vary linearly from 0.0 at $D_b/D_p = 0.75$ to a value of 8.0 at $D_b/D_p = 2.5$, where $D_b$ is the depth below the founding stratum. The top of the founding stratum should be taken at the base of zone of seasonal moisture change.

The assumed variation of $N_u$ is based on Yazdanbod et al. (1987).

This method does not include the uplift resistance contribution due to soil suction and the weight of the shaft.

*10.8.3.7.3—Group Uplift Resistance*

The provisions of Article 10.7.3.11 shall apply.

*10.8.3.7.4—Uplift Load Test*

*C10.8.3.7.4*

The provisions of Article 10.7.3.10 shall apply.

See Article C10.7.3.10.

**10.8.3.8—Nominal Horizontal Resistance of Shaft and Shaft Groups**

**C10.8.3.8**

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded drilled shafts shall account for the effects of interaction between the shaft and ground, including the number of shafts in the group.

For shafts used in groups, the drilled shaft head shall be fixed into the cap.

See Article C10.7.3.12.

**10.8.3.9—Shaft Structural Resistance**

*10.8.3.9.1—General*

The structural design of drilled shafts shall be in accordance with the provisions of Section 5 for the design of reinforced concrete.

*10.8.3.9.2—Buckling and Lateral Stability*

*C10.8.3.9.2*

The provisions of Article 10.7.3.13.4 shall apply.

See Article C10.7.3.13.4.

*10.8.3.9.3—Reinforcement*

*C10.8.3.9.3*

Where the potential for lateral loading is insignificant, drilled shafts may be reinforced for axial loads only. Those portions of drilled shafts that are not supported laterally shall be designed as reinforced concrete columns in accordance with Article 5.6.4. Reinforcing steel shall extend a minimum of 10.0 ft below the plane where the soil provides fixity.

Where the potential for lateral loading is significant, the unsupported portion of the shaft shall be designed in accordance with Article 5.11.

The minimum spacing between longitudinal bars, as well as between transverse bars or spirals, shall be sufficient to allow free passage of the concrete through the cage and into the annulus between the cage and the borehole wall.

Shafts constructed using generally accepted procedures are not normally stressed to levels such that the allowable concrete stress is exceeded. Exceptions include:

- Shafts with sockets in hard rock,
- Shafts subjected to lateral loads,
- Shafts subjected to uplift loads from expansive soils or direct application of uplift loads, and
- Shafts with unreinforced bells.

Maintenance of the spacing of reinforcement and the maximum aggregate size requirements are important to ensure that the high-slump concrete mixes normally used for drilled shafts can flow readily between the steel bars during concrete placement. See Article 5.12.9.5.2 for specifications regarding the minimum clear spacing required between reinforcing cage bars.

A shaft can be considered laterally supported:

- below the zone of liquefaction or seismic loads,

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- in rock, or
- 5.0 ft below the ground surface or the lowest anticipated scour elevation.

Laterally supported does not mean fixed. Fixity would occur somewhat below this location and depends on the stiffness of the supporting soil.

The out-to-out dimension of the assembled reinforcing cage should be sufficiently smaller than the diameter of the drilled hole to ensure free flow of concrete around the reinforcing as the concrete is placed. See Article 5.12.9.

The minimum requirements to consider the steel shell to be load carrying shall be as specified in Article 5.12.9.5.2.

See commentary to Article 10.7.5 regarding assessment of corrosivity. In addition, consideration should be given to the ability of the concrete and steel shell to bond together.

*10.8.3.9.4—Transverse Reinforcement*

Transverse reinforcement may be constructed as hoops of spiral steel.

Seismic provisions shall be in accordance with Article 5.11.

*10.8.3.9.5—Concrete*

*C10.8.3.9.5*

The maximum aggregate size, slump, wet or dry placement, and necessary design strength should be considered when specifying shaft concrete. The concrete selected should be capable of being placed and adequately consolidated forthe anticipated construction condition, and shaft details should be specified. The maximum size aggregate shall meet the requirements of Article 10.8.3.9.3.

When concrete is placed in shafts, vibration is often not possible except for the uppermost cross-section. Vibration should not be used for high slump concrete.

*10.8.3.9.6—Reinforcement into Superstructure*

Sufficient reinforcement shall be provided at the junction of the shaft with the shaft cap or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

*10.8.3.9.7—Enlarged Bases*

Enlarged bases shall be designed to ensure that the plain concrete is not overstressed. The enlarged base shall slope at a side angle not greater than 30 degrees from the vertical and have a bottom diameter not greater than three times the diameter of the shaft. The thickness of the bottom edge of the enlarged base shall not be less than 6.0 in.

**10.8.4—Extreme Event Limit State**

**C10.8.4**

The provisions of Article 10.5.5.3 and 10.7.4 shall apply.

See Articles C10.5.5.3 and C10.7.4.

© 2020 by the American Association of State Highway and Transportation Officials.

## 10.9—MICROPILES

### 10.9.1—General

The provisions of Article 10.7.1 shall apply, except as noted herein.

Micropiles shall be classified by type based on their method of installation as follows:

- Type A micropiles are constructed by placing a sand-cement mortar or neat cement grout in the pile under a gravity head only;
- Type B micropiles are constructed by injecting a neat cement grout under pressure (typically 6–21 ksf) into the drilled hole while the temporary drill casing or auger is withdrawn;
- Type C micropiles are grouted as for Type A, followed 15–25 min after primary grouting by injection of additional grout under pressure (typically greater than 21 ksf) via a preplaced sleeved grout pipe.
- Type D micropiles are grouted similar to Type C, but the primary grout is allowed to harden before injecting the secondary grout under pressure (typically 42–170 ksf) with a packer to achieve treatment of specific pile intervals or material horizons; or
- Type E micropiles are constructed by drilling with grout injection through a continuous-thread, hollow-core steel bar. The grout injection serves to flush cuttings, achieve grout penetration into the ground and stabilize the drill hole. Often the initial grout has a high water to cement ratio and is then replaced with a thicker structural grout near the completion of drilling.

Primary grout, where it provides direct load transfer along the micropile to the surrounding ground, shall be Portland cement-based grout injected into the micropile hole before or after reinforcement installation.

Post grouting, also known as regrouting or secondary grouting, shall be taken as the injection of additional Portland cement grout into the bond length of the micropile after set up of primary grout to enhance the grout–ground bond.

#### 10.9.1.1—Scope

The provisions of this Article shall apply to the design of micropiles.

The provisions of this section shall not be taken as applicable to drilled piles, e.g., augercast piles, installed with continuous flight augers that are concreted as the auger is being extracted.

### C10.9.1

Micropiles should be considered:

- Where footings cannot be founded on rock, stiff cohesive, or granular foundation material at a reasonable expense;
- At locations where soil conditions would normally permit the use of spread footings, but the potential for erosion exists;
- At locations where pile foundations must penetrate rock;
- At locations where difficult subsurface conditions (e.g., cobbles, boulders, debris fill, running sands) would hinder installation of driven piles or drilled shafts;
- At locations where difficult access or limited headroom preclude use of other deep foundation systems;
- At locations where foundations must bridge over or penetrate subsurface voids;
- Where vibration limits preclude conventional pile driving operations or access by drilled shaft rigs; or
- When underpinning or retrofitting existing foundations.

A typical detail for a composite reinforced micropile is illustrated in Figure C10.9.1-1.

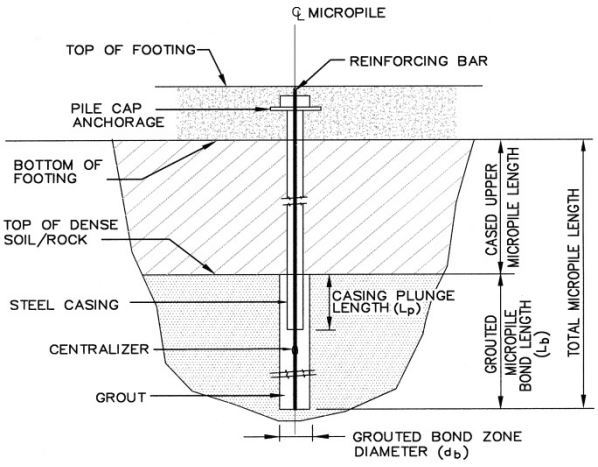

**Figure C10.9.1-1—Typical Detail of Composite Reinforced Micropile *(*after Sabatini et al., 2005)**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 10.9.1.2—Minimum Micropile Spacing, Clearance, and Embedment into Cap

Center-to-center pile spacing should not be less than 30.0 in. or 3.0 pile diameters, whichever is greater. Otherwise, the provisions of Article 10.7.1.2 shall apply.

### 10.9.1.3—Micropiles through Embankment Fill

Micropiles extending through embankments shall penetrate a minimum of 10.0 ft into original ground, unless the required nominal axial and lateral resistance occurs at a lesser penetration below the embankment within bedrock or other suitable support materials.

### C10.9.1.3

If compressible soils are located beneath the embankment, micropiles should be installed after embankment settlement is complete, if possible, to minimize or eliminate downdrag forces.

### 10.9.1.4—Battered Micropiles

The provisions of Article 10.7.1.4 shall apply.

### C10.9.1.4

See Article C10.7.1.4.

### 10.9.1.5—Micropile Design Requirements

Micropile design shall address the following issues as appropriate:

- Nominal axial resistance to be specified in the contract and size of micropile group required to provide adequate support, with consideration of how nominal axial micropile resistance will be determined in the field;
- Group interaction;
- Pile quantity estimation from estimated pile penetration required to meet nominal axial resistance and other design requirements;
- Minimum pile penetration necessary to satisfy the requirements caused by uplift, scour, downdrag, settlement, liquefaction, lateral loads, and seismic conditions;
- Foundation deflection to meet the established movement and associated structure performance criteria;
- Pile foundation nominal structural resistance; and
- Long-term durability of the micropile in service, i.e., corrosion and deterioration.

### C10.9.1.5

The micropile design process is discussed in detail in *Micropile Design and Construction* (Sabatini et al., 2005).

### 10.9.1.6—Determination of Micropile Loads

The provisions of Article 10.7.1.6 shall apply.

### C10.9.1.6

See Article C10.7.1.6.

*10.9.1.6.1—Downdrag*

The provisions of Articles 10.7.1.6.2 and 3.11.8 shall apply.

*C10.9.1.6.1*

See Articles C10.7.1.6.2 and C3.11.8.

*10.9.1.6.2—Uplift Due to Expansive Soils*

The provisions in Article 10.7.1.6.3 shall apply.

*C10.9.1.6.2*

See Article C10.7.1.6.3.

© 2020 by the American Association of State Highway and Transportation Officials.

*10.9.1.6.3—Nearby Structures*

The provisions of Article 10.7.1.6.4 shall apply.

## 10.9.2—Service Limit State Design

### 10.9.2.1—General

**C10.9.2.1**

The provisions of Article 10.7.2.1 shall apply.

See Article C10.7.2.1.

### 10.9.2.2—Tolerable Movements

**C10.9.2.2**

The provisions of Articles 10.5.2.1 and 10.5.2.2 shall apply.

See Articles C10.5.2.1 and C10.5.2.2.

### 10.9.2.3—Settlement

**C10.9.2.3**

The provisions of Article 10.7.2.3 shall apply.

See Article C10.7.2.3.

Methods for calculating the settlement of micropiles are discussed in Sabatini et al. (2005).

*10.9.2.3.1—Micropile Groups in Cohesive Soil*

*C10.9.2.3.1*

The provisions of Article 10.7.2.3.1 shall apply.

See Article 10.7.2.3.1.

*10.9.2.3.2—Micropile Groups in Cohesionless Soil*

*C10.9.2.3.2*

The provisions of Article 10.7.2.3.2 shall apply.

See Article C10.7.2.3.2.

### 10.9.2.4—Horizontal Micropile Foundation Movement

**C10.9.2.4**

The provisions of Articles 10.5.2.1 and 10.7.2.4 shall apply.

See Articles C10.5.2.1 and C10.7.2.4.

### 10.9.2.5—Settlement Due to Downdrag

**C10.9.2.5**

The provisions of Article 10.7.2.5 shall apply.

See Article C10.7.2.5.

### 10.9.2.6—Lateral Squeeze

**C10.9.2.6**

The provisions of Article 10.7.2.6 shall apply.

See Article C10.7.2.6.

## 10.9.3—Strength Limit State Design

### 10.9.3.1—General

**C10.9.3.1**

For strength limit state design, the following shall be determined:

- loads and performance requirements;
- micropile dimensions and nominal axial micropile resistance;
- size and configuration of the micropile group to provide adequate foundation support;
- estimated micropile length to be used in the construction contract documents to provide a basis for bidding;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- a minimum micropile penetration, if required, for the particular site conditions and loading, determined based on the maximum (deepest) penetration needed to meet all of the applicable requirements identified in Article 10.7.6; and
- the nominal structural resistance of the micropile and/or micropile group.

A minimum micropile penetration should only be specified if needed to insure that uplift, lateral stability, depth to resist downdrag, depth to resist scour, and depth for structural lateral resistance are met for the strength limit state, in addition to similar requirements for the service and extreme event limit states. See Article C10.7.6 for additional details.

Punching of micropiles through strong soil into a weaker layer is not likely for micropiles designed for a resistance by bond transfer only.

**10.9.3.2—Ground Water Table and Bouyancy**

**C10.9.3.2**

The provisions of Article 10.7.3.4 shall apply.

See Article C10.7.3.4.

**10.9.3.3—Scour**

**C10.9.3.3**

The provisions of Article 10.7.3.5 shall apply.

See Article C10.7.3.5.

**10.9.3.4—Downdrag**

**C10.9.3.4**

The provisions of Article 10.7.3.6 shall apply.

See Article C10.7.3.6.

**10.9.3.5—Nominal Axial Compression Resistance of a Single Micropile**

*10.9.3.5.1—General*

*C10.9.3.5.1*

Micropiles shall be designed to resist failure of the bonded length in soil and rock, or for micropiles bearing on rock, failure of the rock at the micropile tip.

The factored resistance of a micropile, $R_R$, shall be taken as:

$$R_R = \varphi R_n = \varphi_{qp} R_p + \varphi_{qs} R_s \qquad (10.9.3.5.1\text{-}1)$$

in which:

$$R_p = q_p A_p \qquad (10.9.3.5.1\text{-}2)$$

$$R_s = q_s A_s \qquad (10.9.3.5.1\text{-}3)$$

where:

$\varphi$ = resistance factor (dim)
$R_n$ = nominal sliding resistance against failure by sliding (kips)
$R_p$ = nominal tip resistance (kips)
$R_s$ = nominal grout-to-ground bond resistance (kips)
$\varphi_{qp}$ = resistance factor for tip resistance specified in Table 10.5.5.2.5-1
$\varphi_{qs}$ = resistance factor for grout-to-ground bond resistance specified in Table 10.5.5.2.5-1
$q_p$ = unit tip resistance (ksf)

Micropiles are typically designed based on bond into soil and rock neglecting tip resistance due to their relatively small diameter and high grout-to-ground bond resistance. Tip resistance may be considered for micropiles bearing on hard rock although the axial capacity for this case is often controlled by the structural resistance of the micropile.

Both the tip and bond resistances develop in response to foundation displacement. The maximum values of each are unlikely to occur at the same displacement. The bond resistance is typically fully mobilized at displacements of about 0.1 to 0.4 in. The tip capacity, however, is mobilized after the micropile settles about six percent of its diameter (Jeon and Kulhawy, 2001), and is generally neglected in the design of micropiles in soil.

The methods for estimating micropile axial resistance provided in this article should be used. Micropile strength limit state resistance methods not specifically addressed in this Article for which adequate successful regional or national experience is available may be used, provided adequate information and experience is also available to develop appropriate resistance factors.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$q_s$ = unit grout-to-ground bond resistance (ksf)
$A_p$ = area of micropile tip ($ft^2$)
$A_s$ = area of grout-to-ground bond surface ($ft^2$)

For final design, micropile resistance shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4. The resistance factors for micropiles shall be taken as specified in Table 10.5.5.2.5-1.

*10.9.3.5.2—Estimation of Grout-to-Ground Bond Resistance*

The nominal grout-to-ground bond resistance over the bonded length of a micropile, $R_s$, in kips shall be taken as:

$$R_s = \pi d_b \alpha_b L_b \quad (10.9.3.5.2\text{-}1)$$

where:

$d_b$ = diameter of micropile drill hole through bonded length (ft)
$\alpha_b$ = nominal micropile grout-to-ground bond strength (ksf)
$L_b$ = micropile bonded length (ft)

For final design, micropile capacity shall be verified through the performance of micropile load tests as described in Article 10.9.3.5.4.

*C10.9.3.5.2*

The value of nominal unit grout-to-ground bond strength, either estimated empirically or determined through load testing, is typically taken as the average value over the entire bond length.

Micropile grout-to-ground bond strength is influenced by soil and rock conditions, method of micropile drilling and installation, and grouting pressure. The final micropile geotechnical design should be performed by a specialty contractor qualified to perform micropile design and construction. As a guide, Table C10.9.3.5.2-1 may be used to estimate the nominal (ultimate) unit grout-to-ground bond strength for Types A, B, C, D, and E micropiles bonded into soil and/or rock for preliminary design.

For preliminary design, the grout-to-ground bond resistance of micropiles may be based on the results of micropile load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing, and pervious experience; or estimated using published soil/rock-grout bond guidelines.

All rights reserved. Duplication is a violation of applicable law.

**Table C10.9.3.5.2-1—Summary of Typical $\alpha_b$ Values (Grout-to-Ground Bond) for Preliminary Micropile Design (modified after Sabatini et al., 2005)**

| Soil/Rock Description | Typical Range of Grout-to-Ground Bond Nominal Resistance for Micropile Types[1] (ksf) | | | | |
|---|---|---|---|---|---|
| | Type A | Type B | Type C | Type D | Type E |
| Silt & Clay (some sand) (soft medium plastic) | 0.7–1.4 | 0.7–2.0 | 0.7–2.5 | 0.7–3.0 | 0.7–2.0 |
| Silt & Clay (some sand) (stiff, dense to very dense) | 0.7–2.5 | 1.4–4.0 | 2.0–4.0 | 2.0–4.0 | 1.4–4.0 |
| Sand (some silt) (fine, loose-medium dense) | 1.4–3.0 | 1.4–4.0 | 2.0–4.0 | 2.0–5.0 | 1.4–5.0 |
| Sand (some silt, gravel) (fine-coarse, medium-very dense) | 2.0–4.5 | 2.5–7.5 | 3.0–7.5 | 3.0–8.0 | 2.5–7.5 |
| Gravel (some sand) (medium-very dense) | 2.0–5.5 | 2.5–7.5 | 3.0–7.5 | 3.0–8.0 | 2.5–7.5 |
| Glacial Till (silt, sand, gravel) (medium-very dense, cemented) | 2.0–4.0 | 2.0–6.5 | 2.5–6.5 | 2.5–7.0 | 2.0–6.5 |
| Soft Shales (fresh-moderate fracturing, little to no weathering) | 4.3–11.5 | N/A | N/A | N/A | N/A |
| Slates and Hard Shales (fresh-moderate fracturing, little to no weathering) | 10.8–28.8 | N/A | N/A | N/A | N/A |
| Limestone (fresh-moderate fracturing, little to no weathering) | 21.6–43.2 | N/A | N/A | N/A | N/A |
| Sandstone (fresh-moderate fracturing, little to no weathering) | 10.8–36.0 | N/A | N/A | N/A | N/A |
| Granite and Basalt (fresh-moderate fracturing, little to no weathering) | 28.8–87.7 | N/A | N/A | N/A | N/A |

[1] Refer to Article 10.9.1 for description of micropile types.

*10.9.3.5.3—Estimation of Micropile Tip Resistance in Rock*

The methods used for design of micropiles bearing on rock shall consider the presence, orientation, and condition of discontinuities, weathering profiles, and other similar profiles as they apply at a particular site. The designer shall judge the competency of a rock mass in accordance with the provisions of Article 10.4.6.4.

For micropiles founded on competent rock, tip resistance may be estimated in accordance with the provisions of Article 10.8.3.5.4c.

*C10.9.3.5.3*

Micropiles are generally designed based on bond into rock rather than tip resistance. Tip resistance is generally considered only for micropiles bearing on competent rock.

For micropiles founded on competent rock, the rock is usually so sound that the structural capacity will govern the design.

Weak rock includes some shales and mudstones or poor-quality weathered rocks. The term “weak” has no generally accepted, quantitative definition; therefore, judgment and experience are required to make this determination.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.9.3.5.4—Micropile Load Test*

The load test shall follow the procedures specified in ASTM D1143 for compression and ASTM D3689 for tension. The loading procedure should follow the Quick Load Test Method, unless detailed longer-term load-settlement data is needed, in which case the standard loading procedure should be used. Unless specified otherwise by the Engineer, the pile axial resistance shall be determined from the test data using the Davisson Method as presented in Article 10.7.3.8.2.

The number of load tests required to account for site variability shall be as specified in Article 10.5.5.2.3. The number of test micropiles required should be increased in nonuniform subsurface conditions.

In addition, proof tests loaded to the required factored load shall be performed on one pile per substructure unit or five percent of the piles, whichever is greater, unless specified otherwise by the Engineer.

The resistance factors for axial compressive resistance or axial uplift resistance shall be taken as specified in Table 10.5.5.2.5-1.

*C10.9.3.5.4*

See Article C10.8.3.5.6.

Load Tests on micropiles are performed to determine micropile installation characteristics, evaluate micropile capacity with depth, and establish micropile bond lengths.

During the performance of ASTM tests, the Contractor may perform several load cycles on the test micropile for diagnostic purposes.

Test micropiles may not be required where previous experience exists with the same micropile type and ultimate micropile capacity in similar subsurface conditions. However, load tests can differ even for apparently similar ground conditions. Therefore, care should be exercised in generalizing and extrapolating the test results to other locations.

Test micropiles are frequently planned for each substructure.

With approval of the Engineer, the number of load tests and proof tests can be reduced based on:

- Previous micropile load tests in similar ground using similar methods, or
- Site-specific tests showing much higher than required factored resistance or consistent proof test.

**10.9.3.6—Resistance of Micropile Groups in Compression**

Reduction in resistance from group effects shall be evaluated in accordance with the provisions of Article 10.7.3.9.

**C10.9.3.6**

See Article C10.7.3.9.

**10.9.3.7—Nominal Uplift Resistance of a Single Micropile**

Uplift resistance shall be evaluated when upward loads act on the micropiles. Micropiles subjected to uplift forces shall be investigated for resistance to pullout, for their structural strength, and for the strength of their connection to supported components.

**C10.9.3.7**

Resistance factors in Article 10.5.5.2.5 assume a tension load test is performed. In the event that tension load tests are not performed, the resistance factor for presumptive values may be used or the tension resistance estimated as 50 percent of the compression resistance.

**10.9.3.8—Nominal Uplift Resistance of Micropile Groups**

The provisions of Article 10.7.3.11 shall apply.

**C10.9.3.8**

Group uplift resistance in rock should consider the depth of soil overburden, rock discontinuity spacing and condition, and rock mass shear strength, as well as bond between micropiles and rock.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 10.9.3.9—Nominal Horizontal Resistance of Micropiles and Micropile Groups

The provisions of Article 10.7.3.12 apply.

The design of horizontally loaded micropiles shall account for the effects of interaction between the micropiles and ground, including the number and spacing of micropiles in the group.

For micropiles used in groups, the micropile head shall be embedded into the cap and the degree of fixity shall be considered in the design.

### C10.9.3.9

See Article C10.7.3.12.

### 10.9.3.10—Structural Resistance

*10.9.3.10.1—General*

The structural design of micropiles shall be in accordance with the provisions of Section 5 for the design of reinforced concrete and Section 6 for the design of steel.

The cased and uncased length of each micropile shall be designed to resist the forces distributed to the micropile based on the micropile inclination and spacing.

The resistance factors for structural design shall be as specified in Table 10.5.5.2.5-2.

*C10.9.3.10.1*

Articles 5.8.2.4, 5.6.4, 5.6.6, 5.12.9, and 6.15 provide specific provisions applicable to design of concrete and steel micropiles.

The design of micropiles supporting axial compression load only requires an allowance for unintended eccentricity. This has been accounted for by use of the equations in Article 5.6.4.4 for reinforced concrete columns that already contain an eccentricity allowance.

*10.9.3.10.2—Axial Compressive Resistance*

The upper cased section of a micropile subjected to compression loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to compression loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the pile in the plunge length (if used), as described in Article 10.9.3.10.4.

For micropiles extending through a weak upper soil layer, extending above ground, subject to scour, extending through mines/caves, or extending through soil that may liquefy, the effect of any laterally unsupported length shall be considered in the determination of axial compression resistance.

The factored structural resistance of a micropile to axial compression loading, $R_C$, in kips may be taken as:

$$R_C = \varphi_C R_n \qquad (10.9.3.10.2\text{-}1)$$

where:

$\varphi_C$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of micropiles in axial compression

$R_n$ = nominal axial compression resistance of micropile specified in Articles 10.9.3.10.2a and 10.9.3.10.2b (kips)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.9.3.10.2a—Cased Length*

The factored structural resistance of the upper cased length of a micropile having no unsupported length and loaded in compression, $R_{CC}$, in kips may be taken as:

$$R_{CC} = \varphi_{CC} R_n \quad (10.9.3.10.2a\text{-}1)$$

for which:

$$R_n = 0.85\left[ 0.85 f_c' A_g + f_y \left( A_b + A_c \right) \right] \quad (10.9.3.10.2a\text{-}2)$$

where:

$\varphi_{CC}$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the cased section of a micropile subjected to compression loading
$f'_c$ = specified compressive strength of micropile grout at 28 days unless another age is specified (ksi)
$A_g$ = cross-sectional area of grout within micropile (in.$^2$)
$f_y$ = specified minimum yield strength of reinforcement bar or steel casing, or stress in steel reinforcement bar or casing at a strain of 0.003, whichever is less (ksi)
$A_b$ = cross-sectional area of steel reinforcing bar (in.$^2$)
$A_c$ = cross-sectional area of steel casing (in.$^2$)

*10.9.3.10.2b—Uncased Length*

The factored structural resistance of the lower, uncased length of a micropile having no unsupported length and loaded in compression, $R_{CU}$, in kips may be taken as:

$$R_{CU} = \varphi_{CU} R_n \quad (10.9.3.10.2b\text{-}1)$$

for which:

$$R_n = 0.85\left[ 0.85 f_c' A_g + f_y A_b \right] \quad (10.9.3.10.2b\text{-}2)$$

where:

$\varphi_{CU}$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the uncased section of a micropile subjected to compression loading
$f'_c$ = specified compressive strength of micropile grout at 28 days unless another age is specified (ksi)
$A_g$ = cross-sectional area of grout within micropile (in.$^2$)
$f_y$ = specified minimum yield strength of reinforcement bar or stress in steel reinforcement bar at a strain of 0.003, whichever is less (ksi)
$A_b$ = cross-sectional area of steel reinforcing bar (in.$^2$)

*C10.9.3.10.2a*

The design compressive stress in the steel is limited to the stress at which the strain equals 0.003 to maintain compatibility with the strain in the grout.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.9.3.10.3—Axial Tension Resistance*

The upper cased section of a micropile subjected to tension loading shall be designed structurally to support the full factored load on the micropile. The lower uncased section of a micropile subjected to tension loading shall be designed structurally to support the maximum full factored load on the micropile less the load transferred to the surrounding ground from the cased portion of the micropile in the plunge length, as described in Article 10.9.3.10.4.

The factored structural resistance of a micropile subjected to tension, $R_T$, may be taken as:

$$R_T = \varphi_T R_n \quad (10.9.3.10.3\text{-}1)$$

where:

$\varphi_T$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of a micropile subjected to tension loading (dim)
$R_n$ = nominal axial tension resistance of micropile specified in Articles 10.9.3.10.3a and 10.9.3.10.3b

*10.9.3.10.3a—Cased Length*

The factored structural resistance of the upper cased length of a micropile subjected to tension loading, $R_{TC}$, in kips may be taken as:

$$R_{TC} = \varphi_{TC} R_n \quad (10.9.3.10.3a\text{-}1)$$

for which:

$$R_n = f_y \left( A_b + A_{ct} \right) \quad (10.9.3.10.3a\text{-}2)$$

where:

$\varphi_{TC}$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the cased section of a micropile subjected to tension loading (dim)
$f_y$ = specified minimum yield strength of reinforcement bar or steel casing, whichever is less (ksi)
$A_b$ = cross-sectional area of steel reinforcing bar (in.$^2$)
$A_{ct}$ = cross-sectional area of steel casing considering reduction for threads (in.$^2$)

*C10.9.3.10.3a*

The design compressive stress in the steel is limited to the stress at which the strain equals 0.003 to maintain compatibility with the strain in the grout.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.9.3.10.3b—Uncased Length*

The factored structural resistance of the lower uncased length of a micropile subjected to tension loading, $R_{TU}$, in kips may be taken as:

$$R_{TU} = \varphi_{TU} R_n \quad (10.9.3.10.3b\text{-}1)$$

for which:

$$R_n = f_y A_b \quad (10.9.3.10.3b\text{-}2)$$

where:

$\varphi_{TU}$ = resistance factor specified in Table 10.5.5.2.5-2 for structural resistance of the uncased section of a micropile subjected to tension loading (dim)
$f_y$ = specified minimum yield strength of reinforcement bar (kip)
$A_b$ = cross-sectional area of steel reinforcing bar (in.$^2$)

*10.9.3.10.4—Plunge Length Transfer Load*

The factored axial load transferred to the ground through the plunge length of the cased portion of a micropile, $P_t$, in kips, may be taken as:

$$P_t = \varphi\left[\pi d_b \alpha_b L_p\right] \quad (10.9.3.10.4\text{-}1)$$

where:

$\varphi$ = resistance factor specified in Table 10.5.5.2.5-1 for geotechnical bearing or uplift resistance, as appropriate, of a single micropile
$d_b$ = diameter of micropile drill hole through bonded length (ft)
$\alpha_b$ = nominal micropile grout-to-ground bond strength (ksf)
$L_p$ = micropile casing plunge length (ft)

If load transfer through the plunge length of the cased portion of a micropile is considered to reduce the load on the lower uncased portion of the micropile, the factored axial load on the uncased portion of the micropile in compression or tension, $P_u$, in kips, may be taken as:

$$P_u = Q - P_t \quad (10.9.3.10.4\text{-}2)$$

where:

$Q$ = $\sum \eta_i \gamma_i Q_i$
= total factored axial load on micropile (kips)
$P_t$ = factored axial load transferred to the ground through the plunge length of the cased portion of a micropile from Eq. 10.9.3.10.4-1 (kips)

*C10.9.3.10.4*

An optional procedure for construction of a composite reinforced micropile includes insertion of the pile casing into the top of the grouted bond zone to effect a transition between the upper cased portion to the lower uncased portion of a micropile. The length of casing inserted into the bond zone by the plunge length is shown in Figure C10.9.1-1. As a result, a portion of the factored axial load on a micropile is transferred to the surrounding ground by the cased portion of the pile, reducing the load that must be supported by the weaker uncased portion of the pile. The reduction in load applied to the uncased length is termed the transfer load $P_t$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*10.9.3.10.5—Grout-to-Steel Bond*

Casing-to-grout bond shall be checked and reinforcement bar development length shall be checked in accordance with the provisions of Section 5.

*C10.9.3.10.5*

Grout-to-steel bond does not typically govern micropile design, except for overlap of reinforcing bars into upper casing.

The bond between the cement grout and the reinforcing steel is the mechanism for transfer of the pile load from the reinforcing steel to the ground. Typical ultimate bond values range from 0.15 to 0.25 ksi for smooth bars and pipe, and 0.30 to 0.50 ksi for deformed bars (Armour et al., 2000). Refer to Section 5 for bar development requirements.

As is the case with any reinforcement, the surface condition will affect the attainable bond. A film of rust may be beneficial, but the presence of loose debris or lubricant or paint is not desirable. Normal methods for the handling and storage of reinforcing bars apply to micropile construction. For the permanent casing that is also used to drill the hole, cleaning of the casing surface can occur during drilling, particularly in granular soils.

*10.9.3.10.6—Buckling and Lateral Stability*

The provisions of Article 10.7.3.13.4 shall apply.

*10.9.3.10.7—Reinforcement into Superstructure*

Sufficient reinforcement shall be provided at the junction of the micropile with the micropile footing or column to make a suitable connection. The embedment of the reinforcement into the cap shall comply with the provision for cast-in-place piles in Section 5.

*C10.9.3.10.7*

Refer to Sabatini et al. (2005) for typical micropile to footing connection details.

**10.9.4—Extreme Event Limit State**

The provisions of Articles 10.5.5.3 and 10.7.4 shall apply.

**C10.9.4**

See Articles C10.5.5.3 and C10.7.4.

**10.9.5—Corrosion and Deterioration**

The provisions of Article 10.7.5 shall apply.

**C10.9.5**

Corrosion protection methods and design presented in Article C10.7.5 apply to micropiles as well. In addition, other micropile specific design options including plastic encapsulation of central reinforcing bars is provided in Sabatini (2005).

# APPENDIX A10—SEISMIC ANALYSIS AND DESIGN OF FOUNDATIONS

## A10.1—INVESTIGATION

Slope instability, liquefaction, fill settlement, and increases in lateral earth pressure have often been major factors contributing to bridge damage in earthquakes. These earthquake hazards may be significant design factors for peak earthquake accelerations in excess of 0.1 *g* and should form part of a site-specific investigation if the site conditions and the associated acceleration levels and design concepts suggest that such hazards may be of importance.

## A10.2—FOUNDATION DESIGN

The commonly-accepted practice for the seismic design of foundations is to utlize a pseudo-static approach, where earthquake-induced foundation loads are determined from the reaction forces and moments necessary for structural equilibrium. Although traditional bearing capacity design approaches are also applied, with appropriate capacity reduction factors if a margin of safety against "failure" is desired, a number of factors associated with the dynamic nature of earthquake loading should always be borne in mind.

Under cyclic loading at earthquake frequencies, the strength capable of being mobilized by many soils is greater than the static strength. For unsaturated cohesionless soils, the increase may be about ten percent, whereas for cohesive soils, a 50 percent increase could occur. However, for softer saturated clays and saturated sands, the potential for strength and stiffness degradation under repeated cycles of loading must also be recognized. For bridges classified as Zone 2, the use of static soil strengths for evaluating ultimate foundation capacity provides a small implicit measure of safety and, in most cases, strength and stiffness degradation under repeated loading will not be a problem because of the smaller magnitudes of seismic events. However, for bridges classified as Zones 3 and 4, some attention should be given to the potential for stiffness and strength degradation of site soils when evaluating ultimate foundation capacity for seismic design.

As earthquake loading is transient in nature, "failure" of soil for a short time during a cycle of loading may not be significant. Of perhaps greater concern is the magnitude of the cyclic foundation displacement or rotation associated with soil yield, as this could have a significant influence on structural displacements or bending moments and shear distributions in columns and other members.

As foundation compliance influences the distribution of forces or moments in a structure and affects computation of the natural period, equivalent stiffness factors for foundation systems are often required. In many cases, use is made of various analytical solutions that are available for footings or piles where it is assumed that soil behaves in an elastic medium. In using these formulae, it should be recognized that equivalent elastic moduli for soils are a function of strain amplitude, and for seismic loads modulus values could be significantly less than those appropriate for low levels of seismic loading. Variation of shear modulus with shearing strain amplitude in the case of sands is shown in Figure A10.2-1. Additional discussion of this topic can be found in the *AASHTO Guide Specifications for LRFD Seismic Bridge Design*.

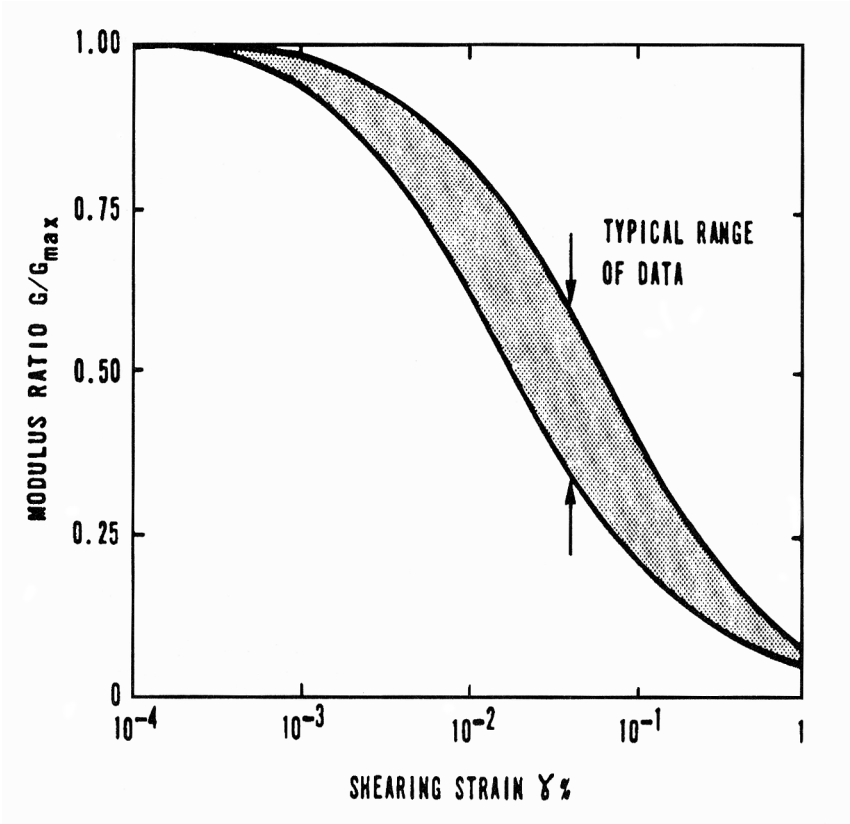

**Figure A10.2-1—Variation of Shear Modulus with Shearing Strain for Sands**

On the basis of field and experimental observations, it is becoming more widely recognized that transient foundation uplift or rocking during earthquake loading, resulting in separation of the foundation from the subsoil, is acceptable provided that appropriate design precautions are taken (Taylor and Williams, 1979). Experimental studies suggest that rotational yielding beneath rocking foundation can provide a useful form of energy dissipation. However, care must be taken to avoid significant induced vertical deformations accompanying possible soil yield during earthquake rocking as well as excessive pier movement. These could lead to design difficulties with relative displacements.

*Lateral Loading of Piles*—Most of the well-known solutions for computing the lateral stiffness of vertical piles are based on the assumption of elastic behavior and utilize equivalent cantilever beam concepts (Davisson and Gill, 1960), the beam on an elastic Inkler foundation method (Matlock and Reese, 1960), or elastic continuum solutions (Poulos, 1971). However, the use of methods incorporating nonlinear subgrade reaction behavior that allows for soil failure may be important for high lateral loading of piles in soft clay and sand. Such a procedure is encompassed in the American Petroleum Institute (API) recommendations for offshore platform design. The method utilizes nonlinear subgrade reaction or *P-y* curves for sands and clays that have been developed experimentally from field loading tests.

The general features of the API analysis in the case of sands are illustrated in Figure A10.2-2. Under large loads, a passive failure zone develops near the pile head. Test data indicate that the ultimate resistance, $p_u$, for lateral loading is reached for pile deflections, $y_u$, of about $3d/80$, where $d$ is the pile diameter. Note that most of the lateral resistance is mobilized over a depth of about $5d$. The API method also recognizes degradation in lateral resistance with cylic loading, although in the case of saturated sands, the degradation postulated does not reflect pore water pressure increases. The degradation in lateral resistance due to earthquake-induced, free-field pore water pressure increases in saturated sands has been described by Finn and Martin (1979). A numerical method that allows the use of API *P-y* curves to compute pile stiffness characteristics forms the basis of the computer program BMCOL 76 described by Bogard and Matlock (1977).

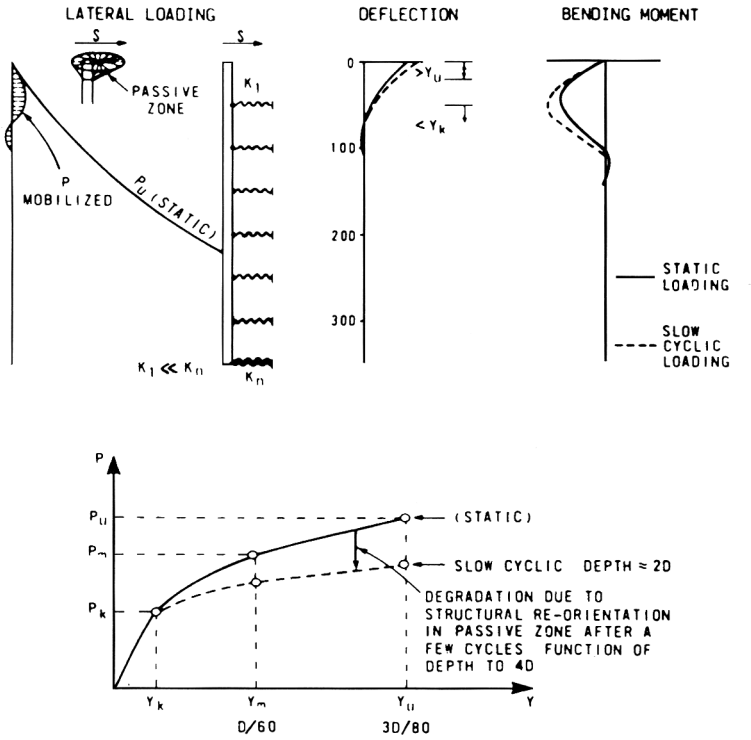

**Figure A10.2-2—Lateral Loading of Piles in Sand Using API Criteria**

The influence of group action on pile stiffness is a somewhat controversial subject. Solutions based on elastic theory can be misleading where yield near the pile head occurs. Experimental evidence tends to suggest that group action is not significant for pile spacings greater than 4*d* to 6*d*.

For batter pile systems, the computation of lateral pile stiffness is complicated by the stiffness of the piles in axial compression and tension. It is also important to recognize that bending deformations in batter pile groups may generate high reaction forces on the pile cap.

It should be noted that although battered piles are economically attractive for resisting horizontal loads, such piles are very rigid in the lateral direction if arranged so that only axial loads are induced. Hence, large relative lateral displacements of the more flexible surrounding soil may occur during the free-field earthquake response of the site (particularly if large changes in soil stiffness occur over the pile length), and these relative displacements may in turn induce high pile bending moments. For this reason, more flexible vertical pipe systems where lateral load is resisted by bending near the pile heads are recommended. However, such pile systems must be designed to be ductile because large lateral displacements may be necessary to resist the lateral load. A compromise design using battered piles spaced some distance apart may provide a system that has the benefits of limited flexibility and the economy of axial load resistance to lateral load.

*Soil-Pile Interaction*—The use of pile stiffness characteristics to determine earthquake-induced pile bending moments based on a pseudo-static approach assumes that moments are induced only by lateral loads arising from inertial effects on the bridge structure. However, it must be remembered that the inertial loads are generated by interaction of the free-field earthquake ground motion with the piles and that the free-field displacements themselves can influence bending moments. This is illustrated in an idealized manner in Figure A10.2-3. The free-field earthquake displacement time histories provide input into the lateral resistance interface elements, which in turn transfer motion to the pile. Near the pile heads, bending moments will be dominated by the lateral interaction loads generated by inertial effects on the bridge structure. At greater depth (e.g., greater than 10*d*), where soil stiffness progressively increases with respect to pile stiffness, the pile will be constrained to deform in a manner similar to that of the free field, and pile bending moments become a function of the curvatures induced by free-field displacements.

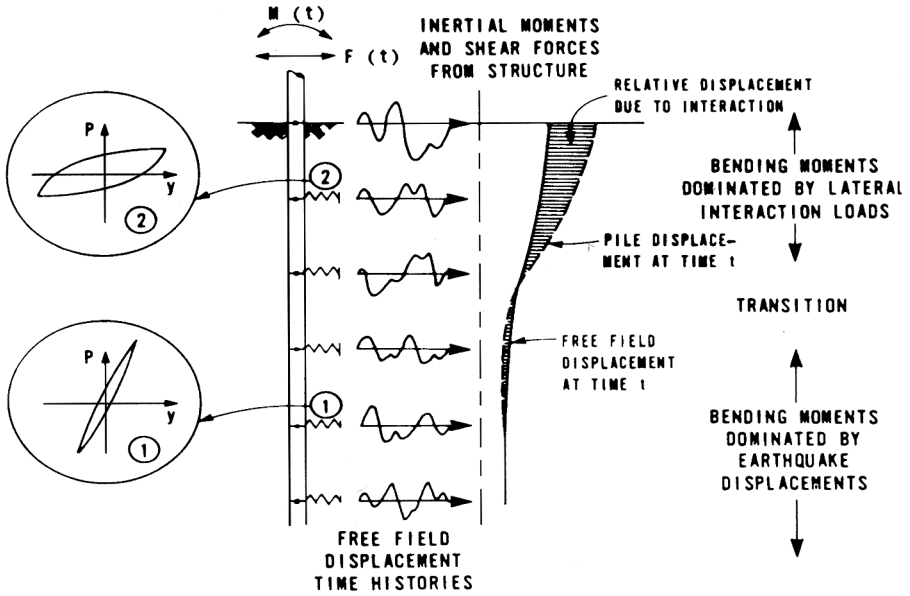

**Figure A10.2-3—Mechanism of Soil-Pile Interaction during Seismic Loading**

To illustrate the nature of free-field displacements, reference is made to Figure A10.2-4, which represents a 200-ft deep cohesionless soil profile subjected to the El Centro earthquake. The free-field response was determined using a nonlinear, one-dimensional response analysis. From the displacement profiles shown at specific times, curvatures can be computed and pile bending moments calculated if it is assumed that the pile is constrained to displace in phase with the free-field response.

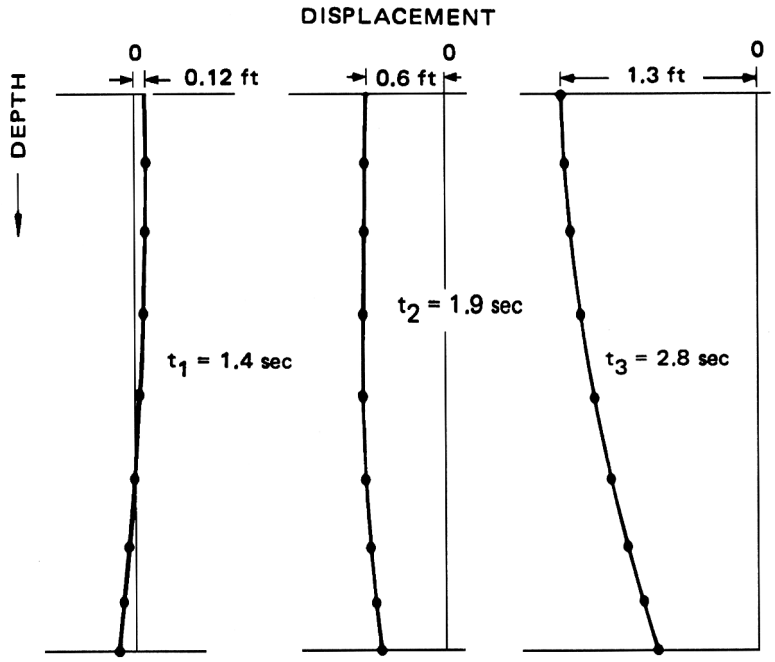

**Figure A10.2-4—Typical Earthquake Displacement Profiles**

Large curvatures could develop at interfaces between soft and rigid soils and, clearly, in such cases emphasis should be placed on using flexible ductile piles. Margason (1979) suggests that curvatures of up to $6 \times 10^{-4}$ in.$^{-1}$ could be induced by strong earthquakes, but these should pose no problem to well-designed steel or prestressed concrete piles.

Studies incorporating the complete soil-pile structure interaction system, as presented in Figure A10.2-3, have been described by Penzien (1970) for a bridge piling system in deep soft clay. A similar but somewhat simpler soil-pile structure interaction system (SPASM) to that used by Penzien has been described by Matlock et al. (1978). The model used is, in effect, a dynamic version of the previously mentioned BMCOL program.

## A10.3—SPECIAL PILE REQUIREMENTS

The uncertainties of ground and bridge response characteristics lead to the desirability of providing tolerant pile and foundation systems. Toughness under induced curvature and shears is required, and hence piles such as steel H-sections and concrete filled steel-cased piles are favored for highly seismic areas. Unreinforced concrete piles are brittle in nature, so nominal longitudinal reinforcing is specified to reduce this hazard. The reinforcing steel should be extended into the footing to tie elements together and to assist in load transfer from the pile to the pile cap.

Experience has shown that reinforced concrete piles tend to hinge or shatter immediately below the pile cap. Hence, tie spacing is reduced in this area so that the concrete is better confined. Driven precast piles should be constructed with considerable spiral confining steel to ensure good shear strength and tolerance of yield curvatures should these be imparted by the soil or structural response. Clearly, it is desirable to ensure that piles do not fail below ground level and that flexural yielding in the columns is forced to occur above ground level. The additional pile design requirements imposed on piles for bridges classified as Zones 3 and 4, for which earthquake loading is more severe, reflect a design philosophy aimed at minimizing below-ground damage that is not easily inspected following a major earthquake.

SECTION 11

# WALLS, ABUTMENTS, AND PIERS

## 11.1—SCOPE

This Section provides requirements for design of abutments and walls. Conventional retaining walls, nongravity cantilevered walls, anchored walls, mechanically stabilized earth (MSE) walls, prefabricated modular walls, and soil nail walls are considered.

## 11.2—DEFINITIONS

*Abutment*—A structure that supports the end of a bridge span, and provides lateral support for fill material on which the roadway rests immediately adjacent to the bridge. In practice, different types of abutments may be used. These include:

- *Stub Abutment*—Stub abutments are located at or near the top of approach fills, with a backwall depth sufficient to accommodate the structure depth and bearings which sit on the bearing seat.
- *Partial-Depth Abutment*—Partial-depth abutments are located approximately at middepth of the front slope of the approach embankment. The higher backwall and wingwalls may retain fill material, or the embankment slope may continue behind the backwall. In the latter case, a structural approach slab or end span design must bridge the space over the fill slope, and curtain walls are provided to close off the open area. Inspection access should be provided for this situation.
- *Full-Depth Abutment*—Full-depth abutments are located at the approximate front toe of the approach embankment, restricting the opening under the structure.
- *Integral Abutment*—Integral abutments are rigidly attached to the superstructure and are supported on a spread footing or a deep foundation capable of permitting necessary horizontal movements.

*Anchored Wall*—An earth retaining system typically composed of the same elements as nongravity cantilevered walls, and that derive additional lateral resistance from one or more tiers of anchors.

*Geogrid*—A geosynthetic formed by a regular network of integrally connected elements with apertures greater than 0.25 in. to allow interlocking with surrounding soil, rock, earth, and other surrounding materials to function primarily as reinforcement.

*Geostrip*—Polymeric material in the form of a strip (also sometimes called a polymer strap) of width not more than 8.0 in., used in contact with soil or other materials in geotechnical and civil engineering applications, or both.

*Geotextile*—A permeable geosynthetic comprised solely of textiles.

*Mechanically Stabilized Earth Wall*—A soil-retaining system, employing either strip- or grid-type, metallic, or polymeric tensile reinforcements in the soil mass, and a facing element that is either vertical or nearly vertical.

*Nongravity Cantilever Wall*—A soil-retaining system that derives lateral resistance through embedment of vertical wall elements and supports retained soil with facing elements. Vertical wall elements may consist of discrete elements, e.g., piles, drilled shafts, or auger-cast piles spanned by a structural facing, e.g., lagging, panels, or shotcrete. Alternatively, the vertical wall elements and facing may be continuous, e.g., sheet piles, diaphragm wall panels, tangent-piles, or tangent drilled shafts.

*Pier*—Part of a bridge structure that provides intermediate support to the superstructure. Different types of piers may be used. These include:

- *Solid Wall Piers*—Solid wall piers are designed as columns for forces and moments acting about the weak axis and as piers for those acting about the strong axis. They may be pinned, fixed, or free at the top, and are conventionally fixed at the base. Short, stubby types are often pinned at the base to eliminate the high moments which would develop due to fixity. Earlier, more massive designs were considered gravity types.

All rights reserved. Duplication is a violation of applicable law.

- *Double Wall Piers*—Double wall piers consist of two separate walls, spaced in the direction of traffic, to provide support at the continuous soffit of concrete box superstructure sections. These walls are integral with the superstructure and must also be designed for the superstructure moments which develop from live loads and erection conditions.
- *Bent Piers*—Bent-type piers consist of two or more transversely spaced columns of various solid cross-sections, and these types are designed for frame action relative to forces acting about the strong axis of the pier. They are usually fixed at the base of the pier and are either integral with the superstructure or with a pier cap at the top. The columns may be supported on a spread- or pile-supported footing, or a solid wall shaft, or they may be extensions of the piles or shaft above the ground line.
- *Single-column Piers*—Single-column piers, often referred to as "T" or "Hammerhead" piers, are usually supported at the base by a spread-, drilled shaft- or pile-supported footing, and may be either integral with, or provide independent support for, the superstructure. Their cross-section can be of various shapes and the column can be prismatic or flared to form the pier cap or to blend with the sectional configuration of the superstructure cross-section. This type of pier can avoid the complexities of skewed supports if integrally framed into the superstructure and their appearance reduces the massiveness often associated with superstructures.
- *Tubular Piers*—A hollow core section which may be of steel, reinforced concrete, or prestressed concrete, of such cross-section to support the forces and moments acting on the elements. Because of their vulnerability to lateral loadings, tubular piers shall be of sufficient wall thickness to sustain the forces and moments for all loading situations as are appropriate. Prismatic configurations may be sectionally precast or prestressed as erected.

*Prefabricated Modular Wall*—A soil-retaining system employing interlocking soil-filled timber, reinforced concrete, or steel modules or bins to resist earth pressures by acting as gravity retaining walls.

*Rigid Gravity and Semi-Gravity (Conventional) Retaining Wall*—A structure that provides lateral support for a mass of soil and that owes its stability primarily to its own weight and to the weight of any soil located directly above its base.

In practice, different types of rigid gravity and semi-gravity retaining walls may be used. These include:

- A *gravity* wall depends entirely on the weight of the stone or concrete masonry and of any soil resting on the masonry for its stability. Only a nominal amount of steel is placed near the exposed faces to prevent surface cracking due to temperature changes.
- A *semi-gravity* wall is somewhat more slender than a gravity wall and requires reinforcement consisting of vertical bars along the inner face and dowels continuing into the footing. It is provided with temperature steel near the exposed face.
- A *cantilever* wall consists of a concrete stem and a concrete base slab, both of which are relatively thin and fully reinforced to resist the moments and shears to which they are subjected.
- A *counterfort* wall consists of a thin concrete face slab, usually vertical, supported at intervals on the inner side by vertical slabs or counterforts that meet the face slab at right angles. Both the face slab and the counterforts are connected to a base slab, and the space above the base slab and between the counterforts is backfilled with soil. All the slabs are fully reinforced.
- A *soil nail wall* is an earth-retaining system containing passive reinforcing elements that are drilled and grouted sub-horizontally in the ground.

## 11.3—NOTATION

### 11.3.1—General

$A_c$ = cross-sectional area of reinforcement unit (in.$^2$) (11.10.6.4.3a)
$A_H$ = cross-sectional area of the head of a stud (in.$^2$) (11.12.6.2.4)
$A'_{HN}$ = equivalent cross-sectional area at the head in the vertical direction (in$^2$) (11.12.6.2.2)
$A_S$ = peak seismic ground acceleration coefficient modified by short-period site factor; cross-sectional area of the shaft of a headed stud (in$^2$) (11.6.5.2.1) (11.6.5.3) (11.12.6.2.4) (A11.3.2) (A11.5.1) (A11.5.2)
$A_t$ = cross-sectional area of soil nail tendon (in$^2$) (11.12.6.1)
$A'_{VN}$ = equivalent cross-sectional area at the head in the horizontal direction (in$^2$) (11.12.6.2.2)
$a_{hm}$ = cross-sectional area of horizontal reinforcement per unit width at midspan of facing (in$^2$/ft) (11.12.6.2.2)
$a_{hn}$ = cross-sectional area of horizontal reinforcement per unit width at nail head (in$^2$/ft) (11.12.6.2.2)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$a_{vm}$ = cross-sectional area of vertical reinforcement per unit width at midspan of facing ($in^2/ft$) (11.12.6.2.2)
$a_{vn}$ = cross-sectional area of vertical reinforcement per unit width at nail head ($in^2/ft$) (11.12.6.2.2)
$B$ = wall base width (ft) (11.10.2)
$b$ = unit width of reinforcement; width of bin module (ft) (11.10.6.4.1) (11.11.5.1)
$b_f$ = width of applied footing load (ft) (11.10.10.2)
$C$ = overall reinforcement surface area geometry factor (dim.) (11.10.6.3.2)
$C_F$ = factor to consider nonuniform soil pressures behind soil nail wall facing (dim.) (11.12.6.2.2)
$C_h$ = coefficient used to determine $z_b$ and $D_{tmax}$ (dim.) (11.10.6.2.1e)
$C_P$ = correction factor to account for contribution of soil support in punching shear (dim.) (11.12.6.2.3)
$CR_{cr}$ = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.) (11.10.6.4.4b)
$CR_u$ = short-term connection strength reduction factor to account for reduced ultimate strength resulting from the connection (dim.) (11.10.6.4.4b)
$C_u$ = coefficient of uniformity defined as ratio of the particle size of soil that is 60 percent finer in size ($D_{60}$) to the particle size of soil that is ten percent finer in size ($D_{10}$) (dim.) (11.10.6.3.2)
$D$ = design embedment depth of vertical element (ft); diameter of bar or wire (in.) (11.10.6.3.2) (C11.8.4.1)
$D'_C$ = effective equivalent diameter of conical slip surface at soil nail head (ft) (11.12.6.2.3)
$D_{DH}$ = drill hole diameter (in.) (11.12.6.2.3) (11.12.5.2)
$D^*$ = diameter of bar or wire corrected for corrosion loss (ft) (11.10.6.4.1)
$D_o$ = embedment for which net passive pressure is sufficient to provide moment equilibrium (ft) (C11.8.4.1)
$D_{SC}$ = diameter of the shaft of a headed stud (in.) (11.12.6.2.4)
$D_{SH}$ = diameter of the head of stud (in.) (11.12.6.2.4)
$D_{tmax}$ = $T_{max}$ distribution factor (dim.) (11.10.6.2.1e)
$D_{tmax0}$ = $T_{max}$ distribution factor magnitude at top of wall at wall face (dim.) (11.10.6.2.1e)
$D_{10}$ = particle size at which 10 percent of the soil particles by weight pass through (in.) (11.10.6.3.2)
$D_{60}$ = particle size at which 60 percent of the soil particles by weight pass through (in.) (11.10.6.3.2)
$d$ = the lateral wall displacement or maximum wall displacement allowed (in.); fill thickness above wall (ft (11.9.4.2) (11.10.10.1) (C11.10.11) (A11.5.1) (A11.5.2) (A11.5.3)
$d_f$ = distance from the outer edge of a final facing section in compression to the centroid of the reinforcement (in.) (11.12.6.2.2)
$d_i$ = distance from the outer edge of an initial facing section in compression to the centroid of the reinforcement (in.) (11.12.6.2.2)
$E_c$ = thickness of metal reinforcement at end of service life (mil.) (11.10.6.4.1)
$E_n$ = nominal thickness of steel reinforcement at construction (mil.) (11.10.6.4.2a)
$E_s$ = sacrificial thickness of metal expected to be lost by uniform corrosion during service life (mil.) (11.10.6.4.2a)
$e$ = eccentricity of load from centerline of foundation (ft) (11.10.6.2.1d)
$F_p$ = static lateral force due to a concentrated surcharge load (kips/ft) (11.6.5.1)
$F_T$ = resultant force of active lateral earth pressure (kips/ft) (11.6.3.2)
$F_v$ = site class adjustment factor for the 1-sec spectral acceleration (dim.) (A11.5.2)
$F_y$ = minimum yield strength of steel (ksi) (11.10.6.4.3a)
$F^*$ = reinforcement pullout friction factor (dim.) (11.10.6.3.2)
$f'_c$ = compressive strength of concrete (ksi) (11.12.6.2.3)
$f_y$ = yield strength of steel (ksi) (11.12.6.1)
$f_{y\text{-}hs}$ = yield strength of headed stud (ksi) (11.12.6.2.4)
$G_u$ = distance from center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft) (11.10.6.4.4b)
$H$ = height of wall (ft) (11.6.5.2.2) (A11.3.1)
$H'$ = 80 percent of the height of the wall, as measured from the bottom of the heel of the wall to the ground surface directly above the wall heel (or the total wall height at the back of the reinforced soil zone for MSE walls) (ft) (A11.5.3)
$H_h$ = hinge height for segmental facing (ft) (11.10.6.4.4b)
$H_{ref}$ = reference wall height (ft) (11.10.6.2.1e)
$H_u$ = segmental facing block unit height (ft) (11.10.6.4.4b)
$H_1$ = equivalent wall height (ft) (11.10.6.3.1)
$h$ = vertical distance between ground surface and wall base at the back of wall heel (ft); thickness of facing (in.) (11.6.3.2) (11.10.6.2.1d) (11.10.7.1) (11.12.6.2.2) (A11.3.1) (A11.5.2)

All rights reserved. Duplication is a violation of applicable law.

$h_a$ = distance between the base of the wall, or the mudline in front of the wall, and the resultant active seismic earth pressure force (ft) (A11.3.1)
$h_c$ = effective depth of conical surface (ft) (11.12.6.2.3)
$h_{eff}$ = equivalent height of an unjointed facing column that is approximately 100 percent efficient in transmitting moment through the height of the facing column (ft) (C11.10.6.2.1e)
$h_f$ = thickness of final facing (in.) (11.12.6.2.2)
$h_i$ = height of reinforced soil zone contributing horizontal load to reinforcement at level $i$ (ft); thickness of initial facing (in.) (11.12.6.2.2)
$h_p$ = vertical distance between the wall base and the static surcharge lateral force, $F_p$ (ft) (11.10.10.1)
$i$ = backfill slope angle (degrees) (A11.3.1)
$i_b$ = slope of facing base downward into backfill (degrees) (11.10.6.4.4b)
$J_{ave}$ = average secant tensile stiffness of all "n" reinforcement layers in wall (kips/ft) (11.10.6.2.1e)
$J_i$ = reinforcement layer secant stiffness (kips/ft) (11.10.4.3)
$K$ = seismic passive pressure coefficient (dim.) (A11.3.1)
$K_{AE}$ = seismic active pressure coefficient (dim.) (A11.3.1)
$k_a$ = active earth pressure coefficient (dim.) (11.8.4.1)
$k_{af}$ = active earth pressure coefficient of backfill (dim.) (11.10.5.2)
$k_{avh}$ = active earth pressure coefficient for a wall with a vertical face (dim.) (11.10.6.2.1e)
$k_h$ = horizontal seismic acceleration coefficient (dim.) (11.6.5.2) (11.8.6.2) (A11.3.1)
$k_{h0}$ = horizontal seismic acceleration coefficient at zero displacement (dim.) (11.6.5.2)
$k_o$ = horizontal at-rest earth pressure coefficient of reinforced fill (dim.) (11.10.6.2.1d)
$k_v$ = vertical seismic acceleration coefficient (dim.) (11.6.5.3) (A11.3.1)
$k_r$ = horizontal earth pressure coefficient of reinforced fill (dim.) (11.10.5.2)
$k_y$ = yield acceleration in sliding block analysis that results in sliding of the wall (dim) (A11.5.2)
$L$ = spacing between vertical elements or facing supports (ft); length of reinforcing elements in an MSE wall and correspondingly its foundation (ft) (C11.8.5.2) (11.10.2)
$L_a$ = length of reinforcement in active zone (ft) (11.10.2)
$L_b$ = anchor bond length (ft) (11.9.4.2)
$L_{BP}$ = length of a bearing plate (ft) (11.12.6.2.3)
$L_e$ = length of reinforcement in resistance zone (ft) (11.10.2)
$L_{ei}$ = effective reinforcement length for layer $i$ (ft) (11.10.7.2)
$L_P$ = pullout length behind slip surface (ft) (11.12.5.2) (C11.12.5.2)
$L_S$ = length of headed stud (ft) (11.12.6.2.4)
$M$ = moment magnitude of design earthquake (dim.) (A11.5.3)
$MARV$ = minimum average roll value (11.10.6.4.3b)
$M_{max}$ = maximum bending moment in vertical wall element or facing (kip-ft or kip-ft/ft) (C11.8.5.2)
$N$ = standard penetration resistance from *SPT* (blows/ft) (A11.5.3)
$N_H$ = number of headed studs (dim.) (11.12.6.2.4)
$n$ = total number of reinforcement layers in the wall (dim) (11.10.6.2.1e) (11.10.7.2)
$P_{AE}$ = dynamic active horizontal thrust, including static earth pressure (kips/ft) (11.6.5.1) (11.10.7.1) (A11.3)
$P_a$ = resultant active earth pressure force per unit width of wall (kips/ft); atmospheric pressure at sea level (ksf) (11.8.6.2) (11.10.6.2.1e)
$P_b$ = pressure inside bin module (ksf) (11.11.5.1)
$PGA$ = peak ground acceleration (dim.) (11.6.5.2.1)
$PGV$ = peak ground velocity (in./sec) (A11.5.2)
$P_H$ = lateral force due to superstructure or other concentrated loads (kips/ft) (11.10.10.1)
$P_i$ = internal inertial force, due to the weight of the backfill within the active zone (kips/ft) (11.10.7.2)
$P_{IR}$ = horizontal inertial force (kips/ft) (11.10.7.1)
$P_{ir}$ = horizontal inertial force caused by acceleration of reinforced backfill (kips/ft) (11.10.7.1)
$P_{is}$ = internal inertial force caused by acceleration of sloping surcharge (kips/ft) (11.10.7.1)
$P_{PE}$ = dynamic passive horizontal thrust, including static earth pressure (kips/ft) (11.8.6.2)
$P_r$ = ultimate soil reinforcement pullout resistance per unit of reinforcement width (kips/ft) (C11.10.6.3.2)
$P_{seis}$ = total lateral force applied to a wall during seismic loading (kips/ft) (11.6.5.1)
$P_v$ = load on strip footing (kips/ft) (11.10.10.1)
$p$ = average lateral pressure, including earth, surcharge, and water pressure, acting on the section of wall element being considered (ksf) (C11.8.5.2)
$Q_n$ = nominal (ultimate) anchor resistance (kips) (11.9.4.2)
$Q_R$ = factored anchor resistance (kips) (11.9.4.2)
$q_s$ = surcharge pressure (ksf) (C11.9.3.1)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$q_u$ = bond strength of soil nails (ksi) (11.12.5.2)
$R$ = resultant force at base of wall (kips/ft) (11.6.3.2)
$R_{BH}$ = basal heave ratio (C11.9.3.1)
$R_c$ = reinforcement coverage ratio (dim.) (11.10.6.3.2) (11.10.6.4.1)
$R_n$ = nominal resistance (kips or kips/ft) (11.5.5)
$R_R$ = factored resistance (kips or kips/ft) (11.5.5)
$RF$ = combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical/biological aging of geosynthetic reinforcements (dim.) (11.10.6.4.3b)
$RF_c$ = combined strength reduction factor for long-term degradation of geosynthetic reinforcement facing connection (dim.) (11.10.6.4.4b)
$RF_{CR}$ = strength reduction factor to prevent long-term creep rupture of reinforcement (dim.) (11.10.6.4.3b)
$RF_D$ = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.) (11.10.6.4.3b)
$R_{FF}$ = nominal resistance of soil nail to flexure (i.e., bending) of facing (kip) (11.12.6.2.2)
$R_{FH}$ = nominal tensile resistance of headed studs located in final facing (kip) (11.12.6.2.4)
$RF_{ID}$ = strength reduction factor to account for installation damage to reinforcement (dim.) (11.10.6.4.3b)
$R_{FP}$ = nominal punching shear resistance of facing (kip) (11.12.6.2.3)
$R_{PO}$ = nominal pullout resistance of soil nail (kip) (11.12.5.2)
$R_T$ = nominal tensile resistance of tendon (kip) (11.12.6.1)
$S$ = average height of soil surcharge within 0.7H of back of wall face (ft) (11.10.6.2.1a)
$S_a$ = the five percent damped spectral acceleration coefficient from the site response spectra (A11.5.3)
$S_{global}$ = global reinforcement stiffness (ksf) (11.10.6.2.1e)
$S_h$ = horizontal reinforcement spacing (ft); horizontal spacing of soil nails (ft) (11.10.6.4.1) (C11.12.1)
$S_{HS}$ = spacing of headed studs (ft) (11.12.6.2.3)
$S_{max}$ = maximum spacing of soil nails (ft) (C11.12.6)
$S_t$ = spacing between transverse grid elements (in.) (11.10.6.3.2)
$S_u$ = undrained shear strength (ksf) (C11.9.5.2)
$S_v$ = vertical spacing of reinforcements, or vertical tributary layer thickness (ft); vertical spacing of soil nails (ft) (11.10.6.2.1b) (11.10.10.1) (C11.12.1)
$S_{rs}$ = ultimate reinforcement tensile resistance required to resist static load component (kips/ft) (11.10.7.2)
$S_{rt}$ = ultimate reinforcement tensile resistance required to resist transient load component (kips/ft) (11.10.7.2)
$S_1$ = 1-sec spectral acceleration coefficient (dim.) (A11.5.2)
$T_{ac}$ = nominal long-term reinforcement/facing connection design strength (kips/ft) (11.10.6.4.1)
$T_{al}$ = nominal long-term reinforcement design strength (kips/ft) (11.10.6.4.1)
$T_{crc}$ = creep-reduced connection strength per unit of reinforcement width determined from the stress rupture envelope at the specified design life as produced from a series of long-term connection creep tests (kips/ft) (11.10.6.4.4b)
$T_{lot}$ = ultimate wide-width tensile strength per unit of reinforcement width (ASTM D4595 or D6637) for the reinforcement material lot used for the connection strength testing (kips/ft) (11.10.6.4.4b)
$T_{max}$ = applied load to reinforcement (kips/ft) (11.10.6.2.1)
$T_{maxsn}$ = maximum soil nail force (kip) (C11.12.2)
$T_{md}$ = factored incremental dynamic inertia force (kips/ft) (11.10.7.2)
$T_{mxmx}$ = the maximum value of reinforcement load $T_{max}$ within the wall section (kips/ft) (C11.10.6.2.1e)
$T_o$ = factored tensile load at reinforcement/facing connection (kips/ft) (11.10.6.2.2)
$T_{osn}$ = tensile force at the nail head (kip) (11.12.6.2.2)
$T_s$ = fundamental period of wall (sec) (A11.5.3)
$T_{total}$ = total load on reinforcement layer (static & dynamic) per unit width of wall (kips/ft) (11.10.7.2)
$T_{totalf}$ = total factored load in the soil reinforcement (kips/ft) (11.10.10.1)
$T_{ult}$ = ultimate tensile strength of reinforcement (kips/ft) (11.10.6.4.3b)
$T_{ultconn}$ = ultimate connection strength per unit of reinforcement width (kips/ft) (11.10.6.4.4b) (11.10.7.2)
$t$ = thickness of transverse elements (in.) (11.10.6.3.2)
$t_P$ = thickness of bearing plate (ft) (11.12.6)
$t_{SH}$ = thickness of the head of stud (ft) (11.12.6.2.4)
$V_F$ = punching shear force acting through facing (kip) (11.12.6.2.3)
$V_s$ = shear wave velocity of the soil behind the wall (ft/sec) (A11.5.3)
$V_1$ = weight of soil carried by wall heel, not including weight of soil surcharge (kips/ft) (11.6.3.2)
$V_2$ = weight of soil surcharge directly above wall heel (kips/ft) (11.6.3.2)
$W_s$ = weight of the soil that is immediately above the wall, including the wall heel (kips/ft) (11.6.5.1)
$W_u$ = unit width of segmental facing (ft) (11.10.6.4.4b)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$W_w$ = weight of the wall (kips/ft) (11.6.5.1)
$W_1$ = weight of wall stem (kips/ft) (11.6.3.2)
$W_2$ = weight of wall footing or base (kips/ft) (11.6.3.2)
$x$ = spacing between vertical element supports (ft) (11.9.5.2)
$Z$ = depth below effective top of wall or to reinforcement (ft) (11.10.6.2.1) (11.10.6.3.2)
$Z_p$ = depth of soil at reinforcement layer at beginning of resistance zone for pullout calculation (ft) (11.10.6.2.1)
$z_b$ = depth below top of wall at wall face where $D_{tmax}$ becomes equal to 1.0 (and below which $D_{tmax}$ equals 1.0) (ft) (11.10.6.2.1e)
$\alpha$ = scale effect correction factor, or wall height acceleration reduction factor for wave scattering (dim.) (11.10.6.3.2) (A11.5.2)
$\beta$ = inclination of ground slope behind face of wall (degrees); slope of backfill (degrees); slope of wall to the vertical, negative as shown (degrees) (11.5.5) (11.10.7.1) (A11.3.1)
$\gamma_{CT}$ = load factor for vehicular impact loads (dim.) (11.10.10.2)
$\gamma_{EQ}$ = load factor for live load applied simultaneously with seismic loads in Article 3.4.1 (dim.) (11.6.5) (C11.5.6)
$\gamma_f$ = unit weight of backfill (kcf) (11.10.5.2)
$\gamma_{LS}$ = load factor for live load surcharge (dim.) (11.10.6.4.1) (B11.2)
$\gamma_P$ = load factor for vertical earth pressure in Article 3.4.1 (dim.) (11.10.6.2.1) (11.12.5.2)
$\gamma_{P\text{-}ES}$ = load factor for earth surcharge (*ES*) in Table 3.4.1-2 (11.10.10.1)
$\gamma_{P\text{-}EV}$ = load factor for vertical earth pressure in Article 3.4.1 (dim.) (11.10.6.2.1)
$\gamma_{p\text{-}EVsf}$ = load factor for prediction of $T_{max}$ for the soil failure limit state (dim.) (11.10.4.3)
$\gamma$ = unit weight of soil (kcf) (A11.3.1)
$\gamma_r$ = unit weight of reinforced fill (kcf) (11.10.6.2.1)
$\gamma_s$ = soil unit weight (kcf)
$\gamma'_s$ = effective soil unit weight (kcf) (C11.8.4.1)
$\gamma_{seis}$ = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load for Extreme Event I (dim.) (11.10.7.2)
$\Delta\sigma_H$ = horizontal stress on reinforcement from concentrated horizontal surcharge (ksf); traffic barrier impact stress applied over reinforcement tributary area (ksf) (11.10.6.2.1) (11.10.10.1)
$\Delta\sigma_v$ = vertical stress due to footing load (ksf) (11.10.10.1)
$\delta$ = wall–backfill interface friction angle (degrees) (11.5.5) (A11.3.1)
$\delta_{max}$ = maximum displacement (ft) (C11.10.4.2)
$\delta_R$ = relative displacement coefficient (C11.10.4.2)
$\varepsilon$ = a normally distributed random variable with zero mean and a standard deviation of 0.66. (A11.5.3)
$\varepsilon_{mxmx}$ = maximum acceptable strain in the wall cross-section corresponding to $T_{max}$ in any reinforcement layer (%) (11.10.4.3)
$\varepsilon_{rein}$ = the reinforcement strain in any individual reinforcement layer corresponding to $T_{max}$ (%) (11.10.4.3)
$\theta$ = wall batter from horizontal (degrees) (C11.10.6.2.1c)
$\theta_{MO}$ = arc tan $[k_h/(1\text{-}k_v)]$ for M–O analysis (degrees) (11.6.5.3) (A11.3.1)
$\rho$ = soil-reinforcement angle of friction (degrees) (11.10.5.3)
$\rho_{ij}$ = reinforcement ratio (percent) (C11.12.6.2.2)
$\sigma_H$ = factored horizontal stress at reinforcement level (ksf) (11.10.6.2.1a)
$\sigma_{Hmax}$ = maximum stress in soil reinforcement in abutment zones (11.10.8)
$\sigma_v$ = vertical stress in soil at reinforcement level of base of wall (ksf) (11.10.6.2.1a)
$\sigma_{V1}$ = vertical soil stress over effective base width (ksf) (11.10.10.1)
$\sigma_1$ = stress at reinforcement level due to MSE wall backfill self-weight (ksf) (11.10.6.2.1a)
$\sigma_2$ = average stress at top of MSE wall backfill due to soil surcharge (ksf) (11.10.6.2.1a)
$\tau_n$ = nominal anchor bond stress (ksf) (11.9.4.2)
$\Phi$ = empirically determined influence factor that captures the effect that the soil reinforcement properties, soil cohesion, and wall geometry have on $T_{max}$ (dim.) (11.10.6.2.1e)
$\Phi_c$ = soil cohesion factor (dim.) (11.10.6.2.1e)
$\Phi_{fb}$ = facing batter factor (dim.) (C11.10.6.2.1)
$\Phi_{fs}$ = facing stiffness factor (dim.) (11.10.6.2.1e)
$\Phi_g$ = global stiffness factor (dim.) (11.10.6.2.1e)
$\Phi_{local}$ = local stiffness factor (dim.) (C11.10.6.2.1e)
$\phi$ = resistance factor (11.5.5) (11.5.7)
$\phi_f$ = internal friction angle of foundation or backfill soil (degrees) (11.10.2) (11.10.5.3) (A11.3.1)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$\phi_{FF}$ = resistance factor for flexure (dim.) (11.12.6.2.2)
$\phi_{FH}$ = resistance factor for headed stud in tension (dim.) (11.12.6.2.4)
$\phi_{FP}$ = resistance factor for punching shear in facing (dim.) (11.12.6.2.3)
$\phi_{PO}$ = resistance factor for pullout (dim.) (11.12.5.2)
$\phi_r$ = internal friction angle of reinforced fill (degrees) (11.10.5.3)
$\phi_{sf}$ = resistance factor that accounts for uncertainty in the measurement of the reinforcement stiffness at the specified strain (dim.) (11.10.4.3)
$\phi_T$ = resistance factor for tension (dim.) (11.5.7)
$\phi'_f$ = effective internal friction angle of soil (degrees) (C11.8.4.1)
$\omega$ = wall batter due to setback of segmental facing units (degrees) (11.10.6.4.4b)

## 11.4—SOIL PROPERTIES AND MATERIALS

### 11.4.1—General

Backfill materials should be granular, free-draining materials. Where walls retain in-situ cohesive soils, drainage shall be provided to reduce hydrostatic water pressure behind the wall.

**C11.4.1**

Much of the knowledge and experience with MSE structures has been with select, cohesionless backfill as specified in Section 7 of the *AASHTO LRFD Bridge Construction Specifications*. Hence, knowledge about internal stress distribution, pullout resistance and failure surface shape is constrained and influenced by the unique engineering properties of granular soils. While cohesive soils have been successfully used, problems including excessive deformation and complete collapse have also occurred. Most of these problems have been attributed to poor drainage. Drainage requirements for walls constructed with poor draining soils are provided in Berg et al. (2009).

### 11.4.2—Determination of Soil Properties

The provisions of Articles 2.4 and 10.4 shall apply.

**C11.4.2**

Also see Article C10.4.

## 11.5—LIMIT STATES AND RESISTANCE FACTORS

### 11.5.1—General

Design of abutments, piers, and walls shall satisfy the criteria for the service limit state specified in Article 11.5.2, and for the strength limit state specified in Article 11.5.3.

Abutments, piers, and retaining walls shall be designed to withstand lateral earth and water pressures, including any live and dead load surcharge, the self-weight of the wall, temperature and shrinkage effects, and earthquake loads in accordance with the general principles specified in this Section.

**C11.5.1**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Earth retaining structures shall be designed for a service life based on consideration of the potential long-term effects of material deterioration, seepage, stray currents, and other potentially deleterious environmental factors on each of the material components comprising the structure. For most applications, permanent retaining walls should be designed for a minimum service life of 75 years. Retaining wall applications defined as temporary shall be considered to have a service life of 36 months or less.

A greater level of safety and/or longer service life, i.e., 100 years, may be appropriate for walls which support bridge abutments, buildings, critical utilities, or other facilities for which the consequences of poor performance or failure would be severe.

Permanent structures shall be designed to retain an aesthetically pleasing appearance and be essentially maintenance free throughout their design service life.

Design of walls to be essentially maintenance free does not preclude the need for periodic inspection of the wall to assess its condition throughout its design life.

**11.5.2—Service Limit States**

Abutments, piers, and walls shall be investigated for excessive vertical and lateral displacement at the service limit state. Tolerable vertical and lateral deformation criteria for retaining walls shall be developed based on the function and type of wall, anticipated service life, and both structural and aesthetic consequences of unacceptable movements to the wall and any potentially affected nearby structures.

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply to the investigation of vertical wall movements. For anchored walls, deflections shall be estimated in accordance with the provisions of Article 11.9.3.1. For MSE walls, deflections shall be estimated in accordance with the provisions of Article 11.10.4.

**C11.5.2**

Vertical wall movements are primarily the result of soil settlement beneath the wall. For gravity and semigravity walls, lateral movement results from a combination of differential vertical settlement between the heel and the toe of the wall and the rotation necessary to develop active earth pressure conditions (see Article C3.11.1).

Tolerable total and differential vertical deformations for a particular retaining wall are dependent on the ability of the wall to deflect without causing damage to the wall elements or adjacent structures, or without exhibiting unsightly deformations.

Surveys of the performance of bridges indicate that horizontal abutment movements less than 1.5 in. can usually be tolerated by bridge superstructures without significant damage, as reported in Bozozuk (1978); Walkinshaw (1978); Moulton et al. (1985); and Wahls (1990). Earth pressures used in design of abutments should be selected consistent with the requirement that the abutment should not move more than 1.5 in. laterally.

Regarding impact to the wall itself, differential settlement along the length of the wall and to some extent from front to back of wall is the best indicator of the potential for retaining wall structural damage or overstress. Wall facing stiffness and ability to adjust incrementally to movement affect the ability of a given wall system to tolerate differential movements. The total and differential vertical deformation of a retaining wall should be small for rigid gravity and semigravity retaining walls, and for soldier pile walls with a cast-in-place facing. For walls with anchors, any downward movement can cause significant stress relaxation of the anchors.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

MSE walls can tolerate larger total and differential vertical deflections than rigid walls. The amount of total and differential vertical deflection that can be tolerated depends on the wall facing material, configuration, and timing of facing construction. A cast-in-place facing has the same vertical deformation limitations as the more rigid retaining wall systems. However, an MSE wall with a cast-in-place facing can be specified with a waiting period before the cast-in-place facing is constructed so that vertical (as well as horizontal) deformations have time to occur. An MSE wall with welded wire or geosynthetic facing can tolerate the most deformation. The deformation tolerance of other MSE wall facing systems, such as precast concrete panels and dry cast concrete blocks, depends on the spacing or cushioning provided between the facing elements and their dimensions, and guidance is provided in Article C11.10.4.1.

### 11.5.3—Strength Limit State

Abutments, walls, and piers shall be investigated at the strength limit states using Eq. 1.3.2.1-1 for:

- bearing resistance failure,
- lateral sliding,
- loss of base contact due to eccentric loading,
- pullout failure of anchors or soil reinforcements,
- structural failure, and
- overall stability.

### 11.5.4—Extreme Event Limit State

#### 11.5.4.1—General Requirements

Abutments, walls, and piers shall be investigated at the extreme event limit state for:

- overall stability failure,
- bearing resistance failure,
- lateral sliding,
- loss of base contact due to eccentric loading,
- pullout failure of anchors or soil reinforcements, and
- structural failure.

The site-adjusted peak ground acceleration, $A_s$ (i.e., $F_{pga} \times PGA$, as specified in Article 3.10.3.2), used for seismic design of retaining walls shall be determined in accordance with Article 3.10.

The levels of peak ground acceleration at the ground surface in some areas will be low enough that a check on seismic loading is not required as other limit states will control the design.

#### 11.5.4.2—Extreme Event I, No Analysis

A seismic design shall not be considered mandatory for walls located in Seismic Zones 1 through 3, or for walls at sites where the site adjusted peak ground acceleration, $A_s$, is less than or equal to 0.4*g*, unless one or more of the following is true:

#### C11.5.4.2

Article 11.5.4.2, related to specific seismic zones, may also be considered applicable to the corresponding Seismic design categories (SDC) A, B, and C, if using AASHTO's *Guide Specifications for LRFD Seismic Bridge Design*.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Liquefaction induced lateral spreading or slope failure, or seismically induced slope failure, due to the presence of sensitive clays that lose strength during the seismic shaking, may impact the stability of the wall for the design earthquake.
- The wall supports another structure that is required, based on the applicable design code or specification for the supported structure, to be designed for seismic loading and poor seismic performance of the wall could impact the seismic performance of that structure.

The no-seismic-analysis option should be limited to internal and external seismic stability design of the wall. If the wall is part of a bigger slope, overall seismic stability of the wall and slope combination should still be evaluated.

These no-seismic-analysis provisions shall not be considered applicable to walls functioning as support piers for bridges.

A summary of previous performance of walls in earthquakes, as well as key research findings that provide support for the provisions in Article 11.5.4.2, is provided in Appendix A11. In general, wall performance in past earthquakes has been very good, even in the largest, most damaging earthquakes, and cases where either wall collapse or severe wall displacements have occurred are rare. For those cases where collapse or severe displacement of walls did occur, those cases were mostly limited to situations where significant liquefaction occurred, where soil conditions behind or below the wall were very poor (e.g., soft silts and clays, marginally stable soils, water build up behind the wall) and ground accelerations were high, or where the wall was subjected to direct shear displacement of the fault. Furthermore, most of those failures were limited to walls that were very old. These wall failure situations are all well outside the limits specified in Article 11.5.4.2 where these specifications allow the designer to not conduct a detailed wall seismic design. However, walls meeting the requirements in Article 11.5.4.2 that allow a seismic analysis to not be conducted have demonstrated consistently good performance in past earthquakes.

Based on previous experience, walls that form tunnel portals have tended to exhibit more damage due to earthquakes than free standing walls. It is likely that the presence of the tunnel restricts the ability of the portal wall to move, increasing the seismic forces to which the wall is subjected. Therefore, a more detailed seismic analysis of tunnel portal walls should be considered even if the walls meet all the other no seismic analysis conditions specified in Article 11.5.4.2.

For walls that cross an active fault which could result in significant differential movement within the wall, a detailed seismic analysis should be considered even if the wall is located in Seismic Zones 1, 2, or 3.

Examples of other structures include bridges (e.g., the abutment foundation), buildings, pipelines or major utilities, pipe arches, or dams. If the wall supports another wall, a seismic design is not required for the lower wall, provided that the upper and lower wall can be designed as a single tiered structure and the limitations on the tiered structure for the provisions in Article 11.5.4.2, if in Seismic Zone 3 or lower, are met.

Based on past experience in earthquakes, wall corners and short-radius turns, defined as an alignment change with an enclosed angle of 120 degrees or less, tend to exhibit greater damage than free standing walls with generally straight alignments due to potentially greater stiffness at the corner, or may separate at the corner due to lack of connectivity between wall sections at the corner. The seismic details discussed in Articles C11.6.5.6 and C11.10.7.4 will help to reduce the potential problems at corners that have occurred in past earthquakes. Note that the enclosed angle of the corner or short-radius turn can either be internal or external to the wall.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

A seismic analysis should be considered for Seismic Zone 2 or higher if either of the following is greater than 30.0 ft:

- the exposed wall height plus the average depth over the width of the wall of any soil surcharge present, or
- for tiered walls, the sum of the exposed height of all the tiers plus the average soil surcharge depth.

A seismic analysis should be considered if in Seismic Zone 2 or higher, and if, for gravity and semigravity walls, the wall backfill does not meet the requirements of Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, due to the possibility that the backfill will not be adequately drained to prevent water build up in the backfill.

For Seismic Zone 2 or higher, if a seismic design is not conducted, it is still important to use good seismic details as specified in Articles 11.6.5.6 and 11.10.7.4.

If the wall is part of a bigger slope that potentially could fail during seismic loading, the overall seismic stability of the wall and slope as defined in Article 11.6.3.7 should be evaluated, as specified in Articles 11.5.4.1 and 11.5.8. If the wall is determined to have only a minor destabilizing effect on the overall stability of the slope during seismic loading, for example, a wall placed within a large slope or existing landslide that is marginally stable during static loading, it may not be practical to design the wall to be stable for overall stability for the Extreme Event I limit state. Addressing the landslide overall stability during seismic loading should be considered a separate effort not specifically addressed by these Specifications.

### 11.5.5—Resistance Requirement

Abutments, piers, and retaining structures and their foundations and other supporting elements shall be proportioned by the appropriate methods specified in Articles 11.6, 11.7, 11.8, 11.9, 11.10, 11.11, or 11.12 so that their resistance satisfies Article 11.5.6.

The factored resistance, $R_R$, calculated for each applicable limit state shall be the nominal resistance, $R_n$, multiplied by an appropriate resistance factor, $\phi$, specified in Table 11.5.7-1.

### C11.5.5

Procedures for calculating nominal resistance are provided in Articles 11.6, 11.7, 11.8, 11.9, 11.10, 11.11, and 11.12 for abutments and retaining walls, piers, nongravity cantilevered walls, anchored walls, mechanically stabilized earth walls, prefabricated modular walls, and soil nail walls, respectively.

### 11.5.6—Load Combinations and Load Factors

Abutments, piers, and retaining structures and their foundations and other supporting elements shall be proportioned for all applicable load combinations specified in Article 3.4.1.

### C11.5.6

Figures C11.5.6-1 and C11.5.6-2 show the typical application of load factors to produce the total extreme factored force effect for external stability of retaining walls for the strength limit state. Where live load surcharge is applicable, the factored surcharge force is generally included over the backfill immediately above the wall only for evaluation of foundation bearing resistance and structure design, as shown in Figure C11.5.6-3. The live load surcharge is not included over the backfill for

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

evaluation of eccentricity, sliding or other failure mechanisms for which such surcharge would represent added resistance to failure. Likewise, the live load on a bridge abutment is included only for evaluation of foundation bearing resistance and structure design. The load factor for live load surcharge is the same for both vertical and horizontal load effects. Figure C11.5.6-3 is also applicable to seismic loading (i.e., Extreme Event I), except that the load factor for live load surcharge is $\gamma_{EQ}$ instead of *LS*.

Figure C11.5.6-4 shows the typical application of load factors to produce the total extreme factored force effect for external stability of retaining walls for the Extreme Event I limit state.

The permanent and transient loads and forces shown in the figures include, but are not limited to:

- Permanent Loads

  *DC* = dead load of structural components and nonstructural attachments
  *DW* = dead load of wearing surfaces and utilities
  *EH* = horizontal earth pressure load
  *ES* = earth surcharge load
  *EV* = vertical pressure from dead load of earth fill

- Transient Loads

  *LS* = live load surcharge
  *WA* = water load and stream pressure

Loads due to water and stream pressure are not shown in these figures. However, the load factor *WA* as specified in Table 3.4.1-1 is always 1.0. Design specifications to account for the destabilizing effect caused by the presence of water are provided in Article 3.11.3.

For the Extreme Event I limit state, the peak seismic lateral pressures acting on the wall should not be based on the maximum ground water elevation due to the low probability that the design peak seismic acceleration would be combined with the maximum ground water level. Instead, it is more appropriate to use the time-averaged mean groundwater elevation or a reasonable engineering estimate of this elevation.

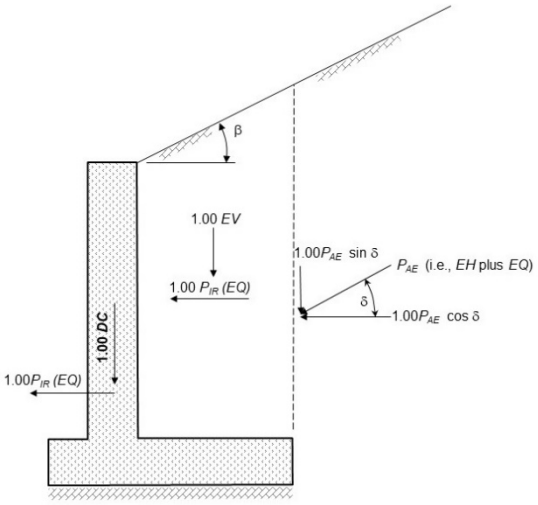

**Figure C11.5.6-4—Typical Application of Load Factors for Bearing and Sliding Resistance and for Eccentricity in the Extreme Event I Limit State**

For seismic loading effects on lateral earth pressure, the seismic load factor shall be applied to the entire lateral earth pressure load created by the earth mass retained by the wall or abutment. For any surcharge loads acting on the wall (e.g., *ES*) in combination with seismic load, *EQ*, the load factor for seismic loads, shall be applied.

Seismic loading of an earth mass retained by a wall is calculated using an extension of Coulomb theory or by limit equilibrium slope stability methods. The seismic loading causes the active soil wedge to increase, resulting in increased total load. The static loading cannot be separated from the seismic loading in this analysis, other than by artificial means through subtracting the static earth pressure from the total earth pressure calculated for seismic loading. Past allowable stress design practice has been to apply a single reduced safety factor to the entire lateral earth load combination. Therefore, one seismic load factor (typically a load factor of 1.0) is applied to the total earth pressure that occurs during seismic loading.

Regarding other loads acting in combination with the seismic loading and earth pressure, the load combination philosophy described for earth pressure also applies to be consistent with past allowable stress design practice for a no collapse design objective.

### 11.5.7—Resistance Factors—Service and Strength

Resistance factors for the service limit states shall be taken as 1.0.

For the strength limit state, the resistance factors provided in Table 11.5.7-1 shall be used for wall design, unless region-specific values or substantial successful experience is available to justify higher values. Resistance factors for geotechnical design of foundations that may be needed for wall support, unless specifically identified in Table 11.5.7-1, are as specified in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, and 10.5.5.2.4-1.

If methods other than those prescribed in these Specifications are used to estimate resistance, the resistance factors chosen shall provide the same reliability as those given in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and Table 11.5.7-1.

### C11.5.7

The resistance factors given in Table 11.5.7-1 for steel reinforced MSE walls, other than those referenced back to Section 10, were calculated by direct correlation to allowable stress design rather than reliability theory. However, for geosynthetic reinforced walls, since the specified method for calculating reinforcement loads is relatively new (i.e., the Stiffness Method—see Article 11.10.6.2.1), reliability theory calibrated resistance factors are provided in Table 11.5.7-1 assuming the load factor for the Stiffness Method ($\gamma_{p\text{-}EV}$), is 1.35. For the Simplified Method, applicable load and resistance factors are provided in Appendix B11.

Comments regarding the differences between extensible and inextensible reinforcement can be found in Article C11.10.6.2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Vertical elements, such as soldier piles, tangent-piles, and slurry trench concrete walls shall be treated as either shallow or deep foundations, as appropriate, for purposes of estimating bearing resistance, using procedures described in Articles 10.6, 10.7, and 10.8.

Some increase in the prescribed resistance factors may be appropriate for design of temporary walls consistent with increased allowable stresses for temporary structures in allowable stress design.

Region-specific resistance factor values should be determined based on substantial statistical data combined with calibration or substantial successful experience to justify higher values. Smaller resistance factors should be used if site or material variability is anticipated to be unusually high or if design assumptions are required that increase design uncertainty that has not been mitigated through conservative selection of design parameters. See Allen et al. (2005) for additional guidance on calibration of resistance factors.

The evaluation of overall stability of walls or earth slopes with or without a foundation unit should be investigated at the strength limit state using $\gamma_p$ for overall stability as specified in Article 3.4.1, and an appropriate resistance factor as specified in Article 11.6.3.7.

All rights reserved. Duplication is a violation of applicable law.

*(Continued from previous page)*

(2) Apply where proof test(s) are conducted on every production anchor to a load of 1.0 or greater times the factored load on the anchor.

(3) Apply to maximum proof test load for the anchor. For mild steel, apply resistance factor to $F_y$. For high-strength steel, apply the resistance factor to guaranteed ultimate tensile strength.

(4) Apply to gross cross-section less sacrificial area. For sections with holes, reduce gross area in accordance with Article 6.8.3 and apply to net section less sacrificial area.

(5) Applies to grid reinforcements connected to a rigid facing element, e.g., a concrete panel or block. For grid reinforcements connected to a flexible facing mat or which are continuous with the facing mat, use the resistance factor for strip reinforcements.

(6) Additional, special cases of limit states, as well as corresponding resistance factors, for soil nail walls are presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al. 2015).

(7) Equivalent to AWS D1.1 Type B studs, with $f_y$ = 60 ksi.

### 11.5.8—Resistance Factors—Extreme Event Limit State

Unless otherwise specified, all resistance factors shall be taken as 1.0 when investigating the extreme event limit state.

For overall stability of the retaining wall when earthquake loading is included, a resistance factor, ϕ, of 0.9 shall be used. For bearing resistance, a resistance factor of 0.8 shall be used for gravity and semigravity walls and 0.9 for MSE walls.

For tensile resistance of metallic reinforcement and connectors, when earthquake loading is included, the following resistance factors shall be used:

- Strip reinforcements, ϕ = 1.0
- Grid reinforcement, ϕ = 0.85

Table 11.5.7-1 Notes 4 and 5 also apply to these resistance factors for metallic reinforcements.

For tensile and pullout resistance of geosynthetic reinforcement and connectors, a resistance factor, ϕ, of 1.0 shall be used.

For pullout resistance of metallic reinforcement, a resistance factor, ϕ, of 1.20 shall be used.

### C11.5.8

A resistance factor of 1.0 is recommended for the extreme event limit state in view of the unlikely occurrence of the loading associated with the design earthquake. The choice of 1.0 is influenced by the following factors:

- For competent soils that are not expected to lose strength during seismic loading (e.g., due to liquefaction of saturated cohesionless soils or strength reduction of sensitive clays), the use of static strengths for seismic loading is usually conservative, as rate-of-loading effects tend to increase soil strength for transient loading.
- Earthquake loads are transient in nature and hence, if soil yield occurs, the net effect is an accumulated small deformation as opposed to foundation failure. This assumes that global stability is adequate.

Using a resistance factor of 1.0 for soil assumes ductile behavior. While this is a correct assumption for many soils, it is inappropriate for brittle soils where there is a significant post-peak strength loss (e.g., stiff over-consolidated clays, sensitive soils). For such conditions, special studies will be required to determine the appropriate combination of resistance factor and soil strength.

For bearing resistance, a slightly lower resistance factor of 0.8 is recommended for gravity and semigravity walls and 0.9 for MSE walls to reduce the possibility that a bearing resistance failure could occur before the wall moves laterally in sliding, reducing the likelihood of excessive wall tilting or collapse, consistent with the design objective of no collapse.

## 11.6—ABUTMENTS AND CONVENTIONAL RETAINING WALLS

### 11.6.1—General Considerations

#### 11.6.1.1—General

Rigid gravity and semigravity retaining walls may be used for bridge substructures or grade separation and are generally for permanent applications.

Rigid gravity and semigravity walls shall not be used without deep foundation support where the bearing soil/rock is prone to excessive total or differential settlement.

#### C11.6.1.1

Conventional retaining walls are generally classified as rigid gravity or semigravity walls, examples of which are shown in Figure C11.6.1.1-1. These types of walls can be effective for both cut and fill wall applications.

Excessive differential settlement, as defined in Article C11.6.2.2, can cause cracking, excessive bending or shear stresses in the wall, or rotation of the wall structure.

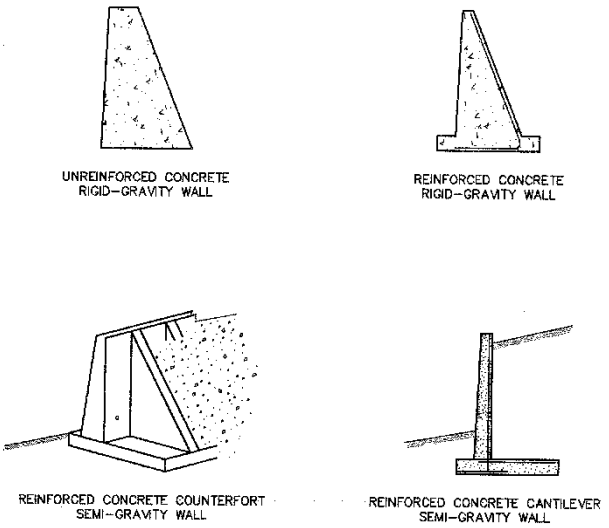

**Figure C11.6.1.1-1—Typical Rigid Gravity and Semigravity Walls**

#### 11.6.1.2—Loading

Abutments and retaining walls shall be investigated for:

- Lateral earth and water pressures, including any live and dead load surcharge;
- The self-weight of the abutment/wall;
- Loads applied from the bridge superstructure;
- Temperature and shrinkage deformation effects; and
- Earthquake loads, as specified herein, in Section 3 and elsewhere in these Specifications.

The provisions of Articles 3.11.5 and 11.5.5 shall apply. For stability computations, the earth loads shall be multiplied by the maximum and/or minimum load factors given in Table 3.4.1-2, as appropriate.

The design shall be investigated for any combination of forces which may produce the most severe condition of loading. The design of abutments on mechanically

#### C11.6.1.2

Cohesive backfills are difficult to compact. Because of the creep of cohesive soils, walls with cohesive backfills designed for active earth pressures will continue to move gradually throughout their lives, especially when the backfill is soaked by rain or rising groundwater levels. Therefore, even if wall movements are tolerable, walls backfilled with cohesive soils should be designed with extreme caution for pressures between the active and

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

stabilized earth and prefabricated modular walls shall be in accordance with Articles 11.10.11 and 11.11.6.

For computing load effects in abutments, the weight of filling material directly over an inclined or stepped rear face, or over the base of a reinforced concrete spread footing may be considered as part of the effective weight of the abutment.

Where spread footings are used, the rear projection shall be designed as a cantilever supported at the abutment stem and loaded with the full weight of the superimposed material, unless a more exact method is used.

### 11.6.1.3—Integral Abutments

Integral abutments shall be designed to resist and/or absorb creep, shrinkage, and thermal deformations of the superstructure.

Movement calculations shall consider temperature, creep, and long-term prestress shortening in determining potential movements of abutments.

To avoid water intrusion behind the abutment, the approach slab should be connected directly to the abutment (not to wingwalls), and appropriate provisions should be made to provide for drainage of any entrapped water.

### 11.6.1.4—Wingwalls

Wingwalls may either be designed as monolithic with the abutments, or be separated from the abutment wall with an expansion joint and designed to be free standing.

The wingwall lengths shall be computed using the required roadway slopes. Wingwalls shall be of sufficient length to retain the roadway embankment and to furnish protection against erosion.

### 11.6.1.5—Reinforcement

*11.6.1.5.1—Conventional Walls and Abutments*

Reinforcement to resist the formation of temperature and shrinkage cracks shall be designed as specified in Article 5.10.6.

*11.6.1.5.2—Wingwalls*

Reinforcing bars or suitable rolled sections shall be spaced across the junction between wingwalls and abutments to tie them together. Such bars shall extend into the masonry on each side of the joint far enough to develop the strength of the bar as specified for bar reinforcement, and shall vary in length so as to avoid planes of weakness in the concrete at their ends. If bars are not used, an expansion joint shall be provided and the wingwall shall be keyed into the body of the abutment.

at-rest cases assuming the most unfavorable conditions. Consideration must be given for the development of pore water pressure within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions should be provided to prevent hydrostatic and seepage forces from developing behind the wall. In no case shall highly-plastic clay be used for backfill.

### C11.6.1.3

Deformations are discussed in Article 3.12.

Integral abutments should not be constructed on spread footings founded or keyed into rock unless one end of the span is free to displace longitudinally.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 11.6.1.6—Expansion and Contraction Joints

Contraction joints shall be provided at intervals not exceeding 30.0 ft and expansion joints at intervals not exceeding 90.0 ft for conventional retaining walls and abutments. All joints shall be filled with approved filling material to ensure the function of the joint. Joints in abutments shall be located approximately midway between the longitudinal members bearing on the abutments.

### 11.6.2—Movement at the Service Limit State

#### 11.6.2.1—Abutments

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 shall apply as applicable.

#### 11.6.2.2—Conventional Retaining Walls

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 apply as applicable.

#### C11.6.2.2

For a conventional reinforced concrete retaining wall, experience suggests that differential wall settlements on the order of 1 in 500 to 1 in 1,000 may overstress the wall.

### 11.6.3—Bearing Resistance and Stability at the Strength Limit State

#### 11.6.3.1—General

Abutments and retaining walls shall be proportioned to ensure stability against bearing capacity failure, overturning, and sliding. Safety against deep-seated foundation failure shall also be investigated, in accordance with the provisions of Article 10.6.3.5.

#### 11.6.3.2—Bearing Resistance

Bearing resistance shall be investigated at the strength limit state using factored loads and resistances, assuming the following soil pressure distributions:

- Where the wall is supported by a soil foundation:

the vertical stress shall be calculated assuming a uniformly distributed pressure over an effective base area as shown in Figure 11.6.3.2-1.

The vertical stress shall be calculated as follows:

$$\sigma_v = \frac{\sum V}{B - 2e} \qquad (11.6.3.2\text{-}1)$$

where:

$\Sigma V$ = the summation of vertical forces, and the other variables are as defined in Figure 11.6.3.2-1

#### C11.6.3.2

See Figure 11.10.10.1-1 for an example of how to calculate the vertical bearing stress where the loading is more complex. Though this figure shows the application of superposition principles to mechanically stabilized earth walls, these principles can also be directly applied to conventional walls.

See Article C11.5.5 for application of load factors for bearing resistance and eccentricity.

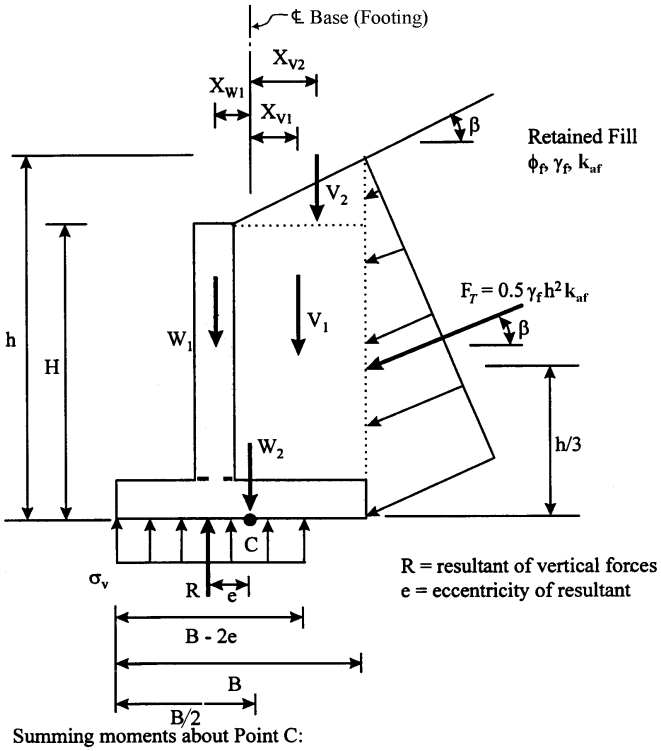
© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Where the wall is supported by a rock foundation:

the vertical stress shall be calculated assuming a linearly distributed pressure over an effective base area as shown in Figure 11.6.3.2-2. If the resultant is within the middle one-third of the base:

$$\sigma_{vmax} = \frac{\sum V}{B}\left(1 + 6\frac{e}{B}\right) \qquad (11.6.3.2\text{-}2)$$

$$\sigma_{vmin} = \frac{\sum V}{B}\left(1 - 6\frac{e}{B}\right) \qquad (11.6.3.2\text{-}3)$$

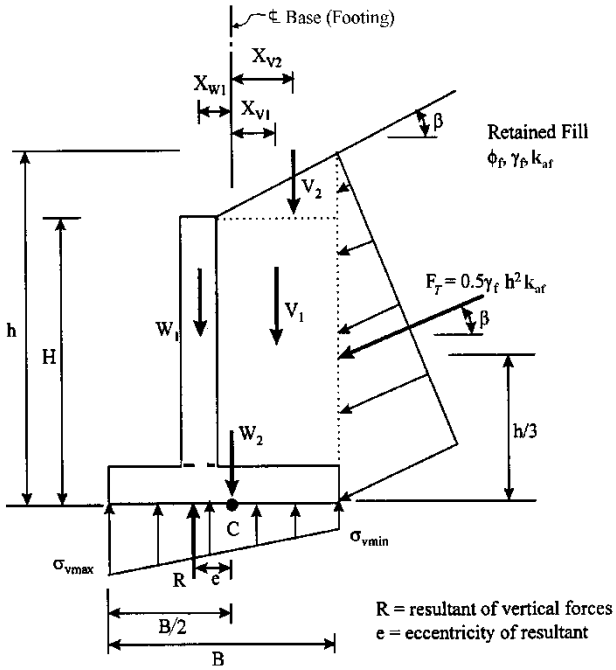


where the variables are as defined in Figure 11.6.3.2-2. If the resultant is outside the middle one-third of the base:

$$\sigma_{vmax} = \frac{2\sum V}{3[(B/2) - e)]} \qquad (11.6.3.2\text{-}4)$$

$$\sigma_{vmin} = 0 \qquad (11.6.3.2\text{-}5)$$

where the variables are as defined in Figure 11.6.3.2-2.



© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Summing moments about Point C:

$$e = \frac{\left(F_T Cos\beta\right)h/3 - \left(F_T \sin\beta\right)B/2 - V_1 X_{V_1} - V_2 X_{V2} + W_1 X_{W1}}{V_1 + V_2 + W_1 + W_2 + F_T \sin\beta}$$

**Figure 11.6.3.2-1—Bearing Stress Criteria for Conventional Wall Foundations on Soil**

If e > B/6, $\sigma_{vmin}$ will drop to zero, and as "e" increases, the portion of the heel of the footing which has zero vertical stress increases.

Summing moments about Point C:

$$e = \frac{\left(F_T Cos\beta\right)h/3 - \left(F_T \sin\beta\right)B/2 - V_1 X_{V_1} - V_2 X_{V2} + W_1 X_{W1}}{V_1 + V_2 + W_1 + W_2 + F_T \sin\beta}$$

**Figure 11.6.3.2-2—Bearing Stress Criteria for Conventional Wall Foundations on Rock**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**11.6.3.3—Eccentricity Limits**

For foundations on soil, the location of the resultant of the reaction forces shall be within the middle two-thirds of the base width.

For foundations on rock, the location of the resultant of the reaction forces shall be within the middle nine-tenths of the base width.

**C11.6.3.3**

The specified criteria for the location of the resultant, coupled with investigation of the bearing pressure, replace the investigation of the ratio of stabilizing moment to overturning moment. Location of the resultant within the middle two-thirds of the base width for foundations on soil is based on the use of plastic bearing pressure distribution for the limit state.

**11.6.3.4—Subsurface Erosion**

For walls constructed along rivers and streams, scour of foundation materials shall be evaluated during design, as specified in Article 2.6.4.4.2. Where potential problem conditions are anticipated, adequate protective measures shall be incorporated in the design.

The provisions of Article 10.6.1.2 shall apply.

The hydraulic gradient shall not exceed:

- For silts and cohesive soils:…….0.20
- For other cohesionless soils:……0.30

Where water seeps beneath a wall, the effects of uplift and seepage forces shall be considered.

**C11.6.3.4**

The measures most commonly used to ensure that piping does not occur are:

- seepage control,
- reduction of hydraulic gradient, and
- protective filters.

Seepage effects may be investigated by constructing a flow net, or in certain circumstances, by using generally accepted simplified methods.

**11.6.3.5—Passive Resistance**

Passive resistance shall be neglected in stability computations, unless the base of the wall extends below the depth of maximum scour, freeze–thaw, or other disturbances. In the latter case, only the embedment below the greater of these depths shall be considered effective.

Where passive resistance is utilized to ensure adequate wall stability, the calculated passive resistance of soil in front of abutments and conventional walls shall be sufficient to prevent unacceptable forward movement of the wall.

The passive resistance shall be neglected if the soil providing passive resistance is, or is likely to become soft, loose, or disturbed, or if the contact between the soil and wall is not tight.

**C11.6.3.5**

Unacceptable deformations may occur before passive resistance is mobilized. Approximate deformations required to mobilize passive resistance are discussed in Article C3.11.1, where $H$ in Table C3.11.1-1 is the effective depth of passive restraint.

**11.6.3.6—Sliding**

The provisions of Article 10.6.3.4 shall apply.

**11.6.3.7—Overall Stability**

The overall stability of the retaining wall, retained slope and foundation soil or rock shall be evaluated using limit equilibrium methods of analysis. The overall stability of temporary cut slopes to facilitate construction shall also be evaluated. Special exploration, testing, and

**C11.6.3.7**

Figure C3.4.1-1 shows a retaining wall overall stability failure. Overall stability for conventional walls (e.g., reinforced concrete gravity and semi-gravity walls) is defined as the stability of a slope soil or rock shear surface that is located outside the back of the wall,

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

analyses may be required for bridge abutments or retaining walls constructed over soft deposits.

The evaluation of overall stability of earth slopes with or without a foundation unit should be investigated at the Strength I Load Combination and an appropriate resistance factor. The resistance factor, ϕ, should be taken as:

- Where the geotechnical parameters and subsurface stratigraphy are well defined ……....0.75
- Where the geotechnical parameters and subsurface stratigraphy are highly variable or based on limited information ……..……...0.65

For anchored walls, MSE walls, and soil nail walls, this Article also applies to compound stability evaluation.

including its footing. In the case of MSE, soil nail, and anchored walls, overall stability for walls is defined as the slope soil or rock shear surface that is located behind the ends of the reinforcement elements (see Article 11.10.5.6 and Figure 11.10.5.6-1). For a definition of compound stability, see Article 11.10.5.6.

The Modified Bishop, simplified Janbu, or Spencer methods of analysis may be used.

Soft soil deposits may be subject to consolidation and/or lateral flow which could result in unacceptable long-term settlements or horizontal movements.

Available slope stability programs produce a single factor of safety, *FS*. The specified resistance factors are essentially the inverse of the *FS* that should be targeted in the slope stability program (i.e., $\phi = 0.75$ approximately corresponds to $FS = 1.3$, and $\phi = 0.65$ approximately corresponds to $FS = 1.5$). These resistance factors address the soil resistance. For anchored walls, MSE walls, and soil nail walls, the resistance factors provided in Article 11.5.7 apply to the resistance of the reinforcement elements.

### 11.6.4—Safety against Structural Failure

The structural design of individual wall elements and wall foundations shall comply with the provisions of Sections 5, 6, 7, and 8.

The provisions of Article 10.6.1.3 shall be used to determine the distribution of contact pressure for structural design of footings.

### 11.6.5—Seismic Design for Abutments and Conventional Retaining Walls

#### 11.6.5.1—General

Rigid gravity and semigravity retaining walls and abutments shall be designed to meet overall stability, external stability, and internal stability requirements during seismic loading. The procedures specified in Article 11.6.3.7 for overall stability, Article 11.6.3 for bearing stability, and Article 10.6.3.4 for sliding stability shall be used but including seismically induced earth pressure and inertial forces, using Extreme Event I limit state load and resistance factors as specified in Article 11.5.8.

For seismic eccentricity evaluation of walls with foundations on soil and rock, the location of the resultant of the reaction forces shall be within the middle two-thirds of the base for $\gamma_{EQ} = 0.0$ and within the middle eight-tenths of the base for $\gamma_{EQ} = 1.0$. For values of $\gamma_{EQ}$ between 0.0 and 1.0, the resultant location restriction shall be obtained by linear interpolation of the values given in this Article.

For bridge abutments, the abutment seismic design should be conducted in accordance with Articles 5.2 and 6.7 of AASHTO's *Guide Specifications*

#### C11.6.5.1

The estimation of seismic design forces should account for wall inertia forces in addition to the equivalent static forces. For semigravity walls in which the footing protrudes behind the back of the wall face (i.e., the heel), the weight of the soil located directly above the heel of the footing should be included in the calculated wall inertial force.

Where a wall supports a bridge structure, the seismic design forces should also include seismic forces transferred from the bridge through bearing supports which do not freely slide, e.g., elastomeric bearings in accordance with Article 14.6.3.

The static lateral earth pressure force acting behind the wall is already included in $P_{AE}$ (i.e., $P_{AE}$ is the combination of the static and seismic lateral earth pressure). See

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*for LRFD Seismic Bridge Design*, but with the following exceptions:

- $k_h$ should be determined as specified in Article 11.6.5.2 and
- lateral earth pressures should be estimated in accordance with Article 11.6.5.3.

To evaluate safety against structural failure (i.e., internal stability) for seismic design, the structural design of the wall elements shall comply with the provisions of Sections 5, 6, 7, and 8.

The total lateral force to be applied to the wall due to seismic and earth pressure loading, $P_{seis}$, should be determined considering the combined effect of $P_{AE}$ and $P_{IR}$, in which:

$$P_{IR} = k_h(W_w + W_s) \qquad (11.6.5.1\text{-}1)$$

and where:

$P_{AE}$ = dynamic lateral earth pressure force
$P_{IR}$ = horizontal inertial force due to seismic loading of the wall mass
$k_h$ = seismic horizontal acceleration coefficient
$W_w$ = the weight of the wall
$W_s$ = the weight of soil that is immediately above the wall, including the wall heel

To investigate the wall stability considering the combined effect of $P_{AE}$ and $P_{IR}$ and considering them not to be concurrent, the following two cases should be investigated:

- combine 100 percent of the seismic earth pressure, $P_{AE}$, with 50 percent of the wall inertial force, $P_{IR}$, and
- combine 50 percent of $P_{AE}$ but no less than the static active earth pressure force (i.e., $F_1$ in Figure 11.10.5.2-1), with 100 percent of the wall inertial force, $P_{IR}$.

The most conservative result from these two analyses should be used for design of the wall. Alternatively, if approved by the Owner, more sophisticated numerical methods may be used to investigate nonconcurrence. For competent soils that do not lose strength under seismic loading, static strength parameters should be used for seismic design.

- For cohesive soils, total stress strength parameters based on undrained tests should be used during the seismic analysis.
- For clean cohesionless soils, the effective stress friction angle should be used.

For sensitive cohesive soils or saturated cohesionless soils, the potential for earthquake-induced strength loss shall be addressed in the analysis.

Article A11.3 for details on the calculation of $P_{AE}$. See Articles 3.11.6.3 and 11.10.10.1 for definitions of terms in Figure 11.6.5.1-1 not specifically defined in this Article.

Since $P_{AE}$ is the combined lateral earth pressure force resulting from static earth pressure plus dynamic effects, the static earth pressure as calculated based on the lateral earth pressure coefficient, $K_a$, should not be added to the seismic earth pressure calculated in Article 11.6.5.3. The static lateral earth pressure coefficient, $K_a$, is, in effect, increased during seismic loading to $K_{AE}$ (see Article 11.6.5.3) due to seismically induced inertial forces on the active wedge, and the potential increase in the volume of the active wedge itself due to flattening of the active failure surface. $P_{AE}$ does not include any additional lateral forces caused by permanent surcharge loads located above the wall (e.g., the static force, $F_p$, and the dynamic force, $k_h W_{\text{surcharge}}$, in Figure 11.6.5.1-1, in which $W_{\text{surcharge}}$ is the weight of the surcharge). If the generalized limit equilibrium method (GLE) is used to calculate seismic lateral earth pressure on the wall, the effect of the surcharge on the total lateral force acting on the wall during seismic loading may, however, be taken directly into account when determining $P_{AE}$. Note that the inertial force due to the weight of the concentrated surcharge load, $k_h W_{\text{surcharge}}$, and the static force, $F_p$, are separate and both act during seismic loading. They must therefore both be included in the seismic wall stability analysis. $F_p$ is calculated as specified in Article 3.11.6.

For evaluating external stability of the wall and for evaluating safety against structural failure of the wall (internal stability), the simplest design approach that will ensure a safe result is to combine the total seismic earth pressure force with the inertial response of the wall section, assuming both are in phase. This approach is conservative in that the peak inertial response of the wall mass is not likely to occur at the same time as the peak seismic active pressure. Previous design practice, at least for MSE walls, has been to combine the full wall inertial force with only 50 percent of the dynamic increment of the total earth pressure (i.e., $P_{AE} - P_A$) to account for this lack of concurrence in the design forces.

Research using centrifuge testing of reduced scale walls by Al Atik and Sitar (2010) indicated that these two seismic forces are out of phase, in that when dynamic earth pressure was at its maximum, the wall inertial force was at its minimum and was very close to zero. When the wall inertial force was at its maximum, the total seismic earth pressure (i.e., $P_{AE}$) was close to its static value. They also indicated, however, that more coincidence between these two forces may still be possible for some wall configurations and ground motions. Nakamura (2006) made similar observations regarding lack of concurrence of these forces based on dynamic centrifuge testing he conducted. This research indicates that treating the two forces as nonconcurrent is justified in most cases.

See Al Atik and Sitar (2010) and Nakamura (2006) for examples of the application of numerical methods to investigate this issue of nonconcurrent forces.

The inertial force associated with the soil mass on the wall heel behind the retaining wall is not added to the

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

active seismic earth pressure when structurally designing the retaining wall. The basis for excluding this inertial force is that movement of this soil mass is assumed to be in phase with the structural wall system with the inertial load transferred through the heel of the wall. Based on typical wave lengths associated with seismic loading, this is considered a reasonable assumption. However, the inertial force for the soil mass over the wall heel is included when determining the external stability of the wall.

Additional discussion and guidance on the selection of soil parameters for seismic design of walls and the potential consideration of soil cohesion are provided by Anderson et al. (2008).

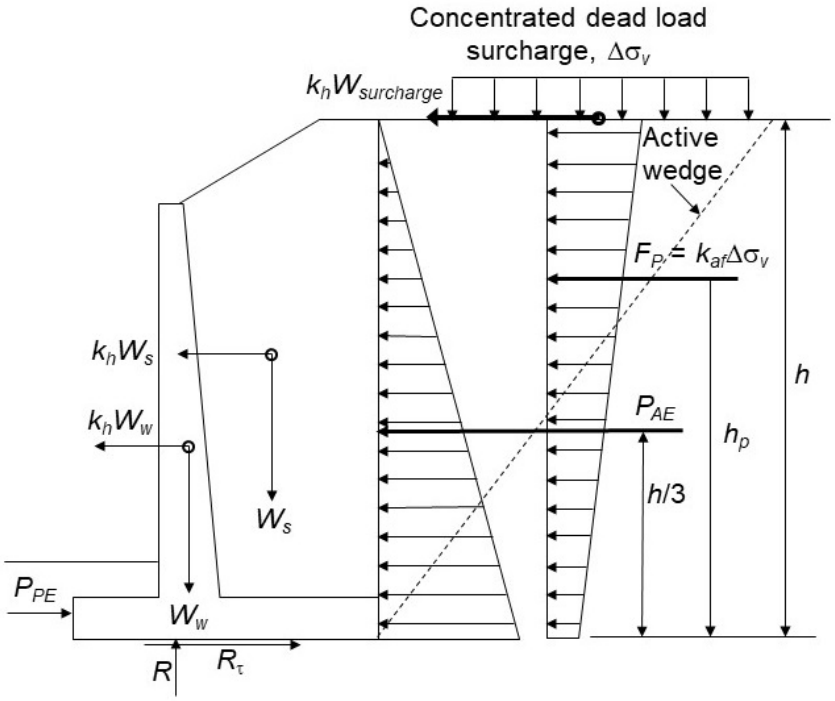


**Figure 11.6.5.1-1—Seismic Force Diagram for Gravity Wall External Stability Evaluation**

### 11.6.5.2—Calculation of Seismic Acceleration Coefficients for Wall Design

*11.6.5.2.1—Characterization of Acceleration at Wall Base*

The seismic horizontal acceleration coefficient, $k_h$, for computation of seismic lateral earth pressures and loads shall be determined on the basis of the *PGA* at the ground surface (i.e., $k_{h0} = F_{pga}\,PGA = A_s$, where $k_{h0}$ is the seismic horizontal acceleration coefficient assuming zero wall displacement occurs). The acceleration coefficient determined at the original ground surface should be considered to be the acceleration coefficient acting at the wall base. For walls founded on Site Class A or B soil (hard or soft rock), $k_{h0}$ shall be based on 1.2 times the site-adjusted peak ground acceleration coefficient (i.e., $k_{h0} = 1.2F_{pga}PGA$).

*C11.6.5.2.1*

$A_s$ is determined as specified in Article 3.10.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The seismic vertical acceleration coefficient, $k_v$, should be assumed to be zero for the purpose of calculating lateral earth pressures, unless the wall is significantly affected by near fault effects (see Article 3.10), or if relatively high vertical accelerations are likely to be acting concurrently with the horizontal acceleration.

In most situations, vertical and horizontal acceleration are at least partially out of phase. Therefore, $k_v$ is usually rather small when $k_h$ is near its maximum value. The typical assumption is to assume that $k_v$ is zero for wall design.

*11.6.5.2.2—Estimation of Acceleration Acting on Wall Mass*

The seismic lateral wall acceleration coefficient, $k_h$, shall be determined considering the effects of wave scattering or ground motion amplification within the wall and the ability of the wall to displace laterally. For wall heights less than 60.0 ft, simplified pseudostatic analyses may be considered acceptable for use in determining the design wall mass acceleration. For wall heights greater than 60.0 ft, special dynamic soil structure interaction design analyses should be performed to assess the effect of spatially varying ground motions within and behind the wall and lateral deformations on the wall mass acceleration.

The height of the wall, $h$, shall be taken as the distance from the bottom of the heel of the retaining structure to the ground surface directly above the heel.

If the wall is free to move laterally under the influence of seismic loading and if lateral wall movement during the design seismic event is acceptable to the Owner, $k_{h0}$ should be reduced to account for the allowed lateral wall deformation. The selection of a maximum acceptable lateral deformation should take into consideration the effect that deformation will have on the stability of the wall under consideration, the desired seismic performance level, and the effect that deformation could have on any facilities or structures supported by the wall. Where the wall is capable of displacements of 1.0 to 2.0 in. or more during the design seismic event, $k_h$ may be reduced to $0.5k_{h0}$ without conducting a deformation analysis using the Newmark method (Newmark, 1965) or a simplified version of it. This reduction in $k_h$ shall also be considered applicable to the investigation of overall stability of the wall and slope.

A Newmark sliding block analysis or a simplified form of that type of analysis should be used to estimate lateral deformation effects, unless the Owner approves the use of more sophisticated numerical analysis methods to establish the relationship between $k_h$ and the wall displacement. Simplified Newmark analyses should only be used if the assumptions used to develop them are valid for the wall under consideration.

*C11.6.5.2.2*

The designer may use $k_h$ for wall design without accounting for wave scattering and lateral deformation effects; however, various studies have shown that the ground motions in the mass of soil behind the wall will often be lower than $k_{h0}$ at the ground surface, particularly for taller walls. However, in some cases, it is possible to have amplification of the ground motion in the wall relative to the wall base ground motion.

The desired performance of walls during a design seismic event can range from allowing limited damage to the wall or displacement of the wall to requiring damage-free, post-earthquake conditions. In many cases, a well-designed gravity or semigravity wall could slide several inches and perhaps even a foot or more, as well as tilt several degrees, without affecting the function of the wall or causing collapse, based on past performance of walls in earthquakes. However, the effect of such deformation on the facilities or structures located above, behind, or in front of the wall must also be considered when establishing an allowable displacement.

Work completed as part of NCHRP Report 611 (Anderson et al., 2008) concluded that, when using the Newmark method, the amount of permanent ground displacement associated with $k_h = 0.5k_{h0}$ will in most cases be less than 1.0 to 2.0 in. (i.e., use of $k_h = 0.5k_{h0}$ provides conservative results).

Details of specific simplified procedures that may be used to estimate wave scattering effects and lateral wall deformations to determine $k_h$ are provided in Appendix A11. Those simplified procedures include Kavazanjian et al. (2003), Anderson et al. (2008), and Bray et al. (2009, 2010). Additional background needed to conduct a full Newmark sliding block analysis is also provided in Appendix A11.

The simplified, Newmark method-based equations mentioned previously present a relatively quick method of estimating the yield acceleration for a given maximum acceptable displacement or, alternatively, the displacements that will occur if the capacity to demand ($C/D$) ratio for a limiting equilibrium stability analysis is less than 1.0. Alternatively, two-dimensional numerical methods that allow seismic time history analyses may be used to estimate permanent displacements. Such models require considerable expertise in the set-up and interpretation of model results, particularly relative to the selection of strength parameters consistent with seismic loading. For this reason, use of this alternate approach should be adopted only with the Owner's concurrence.

### 11.6.5.3—Calculation of Seismic Active Earth Pressures

Seismic active and passive earth pressures for gravity and semigravity retaining walls shall be determined following the methods described in this Article. Site conditions, soil and retaining wall geometry, and the earthquake ground motion determined for the site shall be considered when selecting the most appropriate method to use.

The seismic coefficient, $k_h$, used to calculate seismic earth pressures shall be the site-adjusted peak ground surface acceleration identified in Article 11.6.5.2.1 (i.e., $A_s$) after adjustments for 1) spectral or wave scattering effects and 2) limited amounts of permanent deformation as determined appropriate for the wall and anything the wall movement could affect (Article 11.6.5.2.2). The vertical acceleration coefficient, $k_v$, should be assumed to be zero for design as specified in Article 11.6.5.2.1.

For seismic active earth pressures, either the Mononobe–Okabe (M–O) Method or the Generalized Limit Equilibrium (GLE) Method should be used. For wall geometry or site conditions for which the M–O Method is not suitable, the GLE Method should be used.

The M–O Method shall be considered acceptable for determination of seismic active earth pressures only where:

- the material behind the wall can be reasonably approximated as a uniform, cohesionless soil within a zone defined by a 3H:1V wedge from the heel of the wall,
- the backfill is not saturated and in a loose enough condition such that it can liquefy during shaking, and
- the combination of peak ground acceleration and backslope angle do not exceed the friction angle of the soil behind the wall, as specified in Eq. 11.6.5.3-1.

$$\phi \geq i + \theta_{MO} = i + \arctan\left(\frac{k_h}{1 - k_v}\right) \qquad (11.6.5.3\text{-}1)$$

where:

$\phi$ = the wall backfill friction angle
$i$ = backfill slope angle (degrees)
$k_h$ = the horizontal acceleration coefficient
$k_v$ = the vertical acceleration coefficient

Once $K_{AE}$ is determined, the seismic active force, $P_{AE}$, shall be determined as:

$$P_{AE} = 0.5\ \gamma\ h^2\ K_{AE} \qquad (11.6.5.3\text{-}2)$$

where:

$K_{AE}$ = seismic active earth pressure coefficient (dim)
$\gamma$ = the soil unit weight behind the wall (kips/ft$^3$)

### C11.6.5.3

The suitability of the method used to determine active and passive earth seismic pressures should be determined after a review of features making up the static design, such as backfill soils and slope above the retaining wall. These conditions, along with the ground motion for a site, will affect the method selection.

The complete M–O equation is provided in Appendix A11. The M–O equation for seismic active earth pressure is based on the Coulomb earth pressure theory and is therefore limited to design of walls that have homogeneous, dry cohesionless backfill. The M–O equation has been shown to be most applicable when the backfill is homogenous and can be characterized as cohesionless.

Another important limitation of the M–O equation is that there are combinations of acceleration and slope angle in which real solutions to the equation are no longer possible or that result in values that rapidly approach infinity. The contents of the radical in this equation must be positive for a real solution to be possible. In past practice, when the combination of acceleration and slope angle results in a negative number within the radical in the equation, rather than allowing that quantity to become negative, it was artificially set at zero. While this practice made it possible to get a value of $K_{AE}$, it also tended to produce excessively conservative results. Therefore, in such cases it is better to use an alternative method.

For many situations, gravity and semigravity walls are constructed by cutting into an existing slope where the soil properties differ from the backfill that is used behind the retaining wall. In situations where soil conditions are not homogeneous and the failure surface is flatter than the native slope, seismic active earth pressures computed for the M–O equation using the backfill properties may no longer be valid, particularly if there is a significant difference in properties between the native and backfill soils.

However, the M–O Method has been used in past design practice for estimating seismic earth pressures for many of these situations due to lack of an available alternative. Various approaches to force the method to be usable for such situations have been used, such as estimating some type of average soil property for layered soil conditions or limiting the acceleration to prevent the radical in the equation from being negative, among others. With the exception of seismic passive pressure estimation, this practice has typically resulted in excessively conservative designs and it is not recommended to continue this practice.

The GLE Method consists of conducting a seismic slope stability analysis in which $k_h$ is used as the acceleration coefficient, typically using a computer

$h$ = the total wall height, including any soil surcharge present, at the back of the wall

The external active force computed from the generalized limit equilibrium method, distributed over the wall height $h$, shall be used as the seismic earth pressure.

The equivalent pressure representing the total static and seismic active force ($P_{AE}$) as calculated by either method should be distributed using the same distribution as the static earth pressure used to design the wall when used for external stability evaluations, as illustrated in Figure 11.6.5.1-1, but no less than $H/3$. For the case when a sloping soil surcharge is present behind the wall face ($h$ in Figure 11.6.5.1-1), this force shall be distributed over the total height, $h$.

For complex wall systems or complex site conditions, with the owner's approval, dynamic numerical soil structure interaction (SSI) methods should also be considered.

program in which the applied force necessary to maintain equilibrium (i.e., a capacity/demand ratio of 1.0) under seismic loading is determined. This force is $P_{AE}$. Specific procedures used to conduct this method are provided in Appendix A11. The GLE Method should be used when the M–O Method is not suitable due to the wall geometry, seismic acceleration level, or site conditions.

The Coulomb Wedge Equilibrium Method, also referred to as the trial wedge method, as described in Peck et al. (1974) and Caltrans (2010), may also be used for situations when the M–O Method is not suitable but a hand calculation method is desired, provided that the soil conditions are not too complex (e.g., layered soil conditions behind the wall). Other than the potential ability to use the trial wedge method as a hand calculation method, it has no real advantages over the GLE method.

Studies have indicated that classic limit equilibrium based methods such as the M–O, GLE, and the Coulomb Wedge Equilibrium methods may be overly conservative even if the limitations listed above are considered. See Bray et al. (2010) and Lew et al. (2010a, 2010b) with regard to the generation of seismic earth pressures behind walls and the applicability of the Mononobe–Okabe or similar methods.

For cases in which the wall seismic design result appears to be excessively conservative relative to past experience in earthquakes, other than taking advantage of the no seismic analysis provisions in Article 11.5.4.2, there are no simple solutions; numerical dynamic soil–structure interaction (SSI) modeling may need to be considered. See Bray et al. (2010) for an example. Dynamic numerical SSI solutions may also be needed for more complex wall systems and for walls in which the seismic loading is severe. Due to the complexities of such analyses, an independent peer review of the analysis and results is recommended.

Past practice for locating the resultant of the static and seismic earth pressure for external wall stability has been to either assume a uniform distribution of lateral earth pressure for the combined static plus seismic stress or, if the static and seismic components of earth pressure are treated separately, using an inverted trapezoid for the seismic component, with the seismic force located at 0.6h above the wall base, and combining that force with the normal static earth pressure distribution (Seed and Whitman, 1970). More recent research indicates the location of the resultant of the total earth pressure (static plus seismic) should be located at $h/3$ above the wall base (Clough and Fragaszy, 1977) (Al Atik and Sitar, 2010) (Bray et al., 2010) (Lew et al., 2010a and b). See Appendix A11 for additional discussion on this issue. As a minimum, the combined resultant of the active and seismic earth pressure, i.e., $P_{AE}$, should be located no lower, relative to the wall base, than the static earth pressure resultant. However, a slightly higher combined static/seismic resultant location (e.g., $0.4h$ to $0.5h$) may be considered, since there is limited evidence the resultant could be higher, especially for walls in which the impact of failure is relatively high.

Most natural cohesionless soils have some fines content that contributes cohesion, particularly for short-term loading conditions. Similarly, cohesionless backfills are rarely fully saturated and partial saturation provides for some apparent cohesion, even for most clean sands. The effects of cohesion, whether actual or apparent, are an important issue to be considered in practical design problems.

The M–O equation has been extended to $c$-$\phi$ soils by Prakash and Saran (1966), where solutions were obtained for cases including the effect of tension cracks and wall adhesion. Similar solutions have also been discussed by Richards and Shi (1994) and Chen and Liu (1990).

Results of analyses by Anderson et al. (2008) show a significant reduction in the seismic active pressure for small values of cohesion. From a design perspective, this means that even a small amount of cohesion in the soil could reduce the demand required for retaining wall design.

From a design perspective, the uncertainties in the amount of cohesion or apparent cohesion make it difficult to explicitly incorporate the contributions of cohesion in many situations, particularly in cases where clean backfill materials are being used, regardless of the potential benefits of apparent cohesion that could occur if the soil is partially saturated. Realizing these uncertainties, the following guidelines are suggested.

- Where cohesive soils are being used for backfill or where native soils have a clear cohesive strength component, the designer should give consideration to incorporating some effects of cohesion in the determination of the seismic coefficient.
- If the cohesion in the soil behind the wall results primarily from capillarity stresses, especially in relatively low fines content soils, it is recommended that cohesion be neglected when estimating seismic earth pressure.

The groundwater within the active wedge or submerged conditions (e.g., as in the case of a retaining structure in a harbor or next to a lake or river) can influence the magnitude of the seismic active earth pressure. The time-averaged mean groundwater elevation should be used when assessing groundwater effects.

If the soil within the wedge is fully saturated, then the total unit weight ($\gamma_t$) should be used to estimate the earth pressure when using the M–O Method, under the assumption that the soil and water move as a unit during seismic loading. This situation will apply for soils that are not free draining.

All rights reserved. Duplication is a violation of applicable law.

If the backfill material is a very open granular material, such as quarry spalls, it is possible that the water will not move with the soil during seismic loading. In this case, the effective unit weight should be used in the pressure determination and an additional force component due to hydrodynamic effects should be added to the wall pressure. Various methods are available to estimate the hydrodynamic pressure (see Kramer, 1996). Generally, these methods involve a form of the Westergaard solution.

### 11.6.5.4—Calculation of Seismic Earth Pressure for Nonyielding Abutments and Walls

For abutment walls and other walls that are considered nonyielding, the value of $k_h$ used to calculate seismic earth pressure shall be increased to $1.0k_{h0}$, unless the Owner approves the use of more sophisticated numerical analysis techniques to determine the seismically induced earth pressure acting on the wall, considering the ability of the wall to yield in response to lateral loading. In this case, $k_h$ should not be corrected for wall displacement, since displacement is assumed to be zero. However, $k_h$ should be corrected for wave scattering effects as specified in Article 11.6.5.2.2.

### C11.6.5.4

The lateral earth pressure calculation methodologies provided in Article 11.6.5.3 assume that the abutment or wall is free to laterally yield a sufficient amount to mobilize peak soil strengths in the backfill. Examples of walls that may be nonyielding are integral abutments, abutment walls with structural wing walls, tunnel portal walls, and tied back cylinder pile walls. For granular soils, peak soil strengths can be assumed to be mobilized if deflections at the wall top are about 0.5 percent of the abutment or wall height. For walls restrained from movement by structures, batter piles, or anchors, lateral forces induced by backfill inertial forces could be greater than those calculated by M–O or GLE methods of analysis. Simplified elastic solutions presented by Wood (1973) for rigid nonyielding walls also indicate that pressures are greater than those given by M–O and GLE analysis. These solutions also indicate that a higher resultant location for the combined effect of static and seismic earth pressure of $h/2$ may be warranted for nonyielding abutments and walls and should be considered for design. The use of a factor of 1.0 applied to $k_{h0}$ is recommended for design where doubt exists that an abutment or wall can yield sufficiently to mobilize backfill soil strengths. In general, if the lack of ability of the wall to yield requires that the wall be designed for $K_0$ conditions for the strength limit state, then a $k_h$ of $1.0k_{h0}$ should be used for seismic design.

Alternatively, numerical methods may be used to better quantify the yielding or nonyielding nature of the wall and its effect on the seismic earth pressures that develop, if approved by the Owner.

### 11.6.5.5—Calculation of Seismic Passive Earth Pressure

For estimating seismic passive earth pressures, wall friction and the deformation required to mobilize the passive resistance shall be considered and a log spiral design methodology shall be used. The M–O Method shall not be used for estimating passive seismic earth pressure.

Seismic passive earth pressures shall be estimated using procedures that account for the friction between the retaining wall and the soil, the nonlinear failure surface that develops in the soil during passive pressure loading,

### C11.6.5.5

The seismic passive earth pressure becomes important for walls that develop resistance to sliding from the embedded portion of the wall. For these designs, it is important to estimate passive pressures that are not overly conservative or unconservative for the seismic loading condition. This is particularly the case if displacement-based design methods are used but it can also affect the efficiency of designs based on limit-equilibrium methods.

If the depth of embedment of the retaining wall is less than 5.0 ft, the passive pressure can be estimated using

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

and for wall embedment greater than or equal to 5.0 ft, the inertial forces in the passive pressure zone in front of the wall from the earthquake. For wall embedment depths less than 5.0 ft, passive pressure should be calculated using the static methods provided in Section 3.

In the absence of any specific guidance or research results for seismic loading, a wall interface friction equal to two-thirds of the soil friction angle should be used when calculating seismic passive pressures.

static methods given in Section 3 of these Specifications. For this depth of embedment, the inertial effects from earthquake loading on the development of passive pressures will be small.

For greater depths of embedment, the inertial effects of ground shaking on the development of passive pressures should be considered. This passive zone typically extends three to five times the embedment depth beyond the face of the embedded wall.

Shamsabadi et al. (2007) have developed a methodology for estimating the seismic passive pressures while accounting for wall friction and the nonlinear failure surface within the soil. Appendix A11 of this Section provides charts based on this development for a wall friction of two-thirds of the soil friction angle, $\phi$, and a range of seismic coefficients, $\phi$ values, and soil cohesion, *c*.

The seismic coefficient used in the passive seismic earth pressure calculation is the same value as used for the seismic active earth pressure calculation. Wave scattering reductions are also appropriate to account for incoherency of ground motions in the soil if the depth of the passive zone exceeds 20.0 ft. For most wall designs, the difference between the seismic coefficient behind the wall relative to seismic coefficient of the soil in front of the wall is too small to warrant use of different values.

The M–O equation for seismic passive earth pressure is not recommended for use in determining the seismic passive pressure, despite its apparent simplicity. For passive earth pressure determination, the M–O equation is based on the Coulomb method of determining passive earth pressure; this method can overestimate the earth pressure in some cases.

A key consideration during the determination of static and seismic passive pressures is the wall friction. Common practice is to assume that some wall friction will occur for static loading. The amount of interface friction for static loading is often assumed to range from 50 percent to 80 percent of the soil friction angle. Similar guidance is not available for seismic loading.

Another important consideration when using the seismic passive earth pressure is the amount of deformation required to mobilize this force. The deformation to mobilize the passive earth pressure during static loading is usually assumed to be large—typically 2 percent to 6 percent of the embedded wall height. Similar guidance is not available for seismic loading and therefore the normal approach during design for seismic passive earth pressures is to assume that the displacement to mobilize the seismic passive earth pressure is the same as for static loading.

### 11.6.5.6—Wall Details for Improved Seismic Performance

Details that should be addressed for gravity and semigravity walls in seismically active areas, defined as Seismic Zone 2 or higher, or a peak ground acceleration $A_s$ greater than 0.15$g$, include the following:

- *Vertical Slip Joints, Expansion Joints, and Vertical Joints between an Abutment Curtain Wall and the Free-Standing Wall:* Design to prevent joint from opening up and allowing wall backfill to flow through the open joint without sacrificing the joint's ability to slip to allow differential vertical movement. This also applies to joints at wall corners. Compressible joint fillers, bearing pads, and sealants should be used to minimize damage to facing units due to shaking. The joint should also be designed in a way that allows a minimum amount of relative movement between the adjacent facing units to prevent stress build up between facing units during shaking (Extreme Event I), as well as due to differential deformation between adjacent wall sections at the joint for the service and strength limit states.
- *Coping at Wall Top:* Should be used to prevent toppling of top facing units and excessive differential lateral movement of the facing.
- *Wall Backfill Stability:* Backfill should be well graded and angular enough to interlock/bind together well to minimize risk of fill spilling through open wall joints.
- *Wall Backfill Silt and Clay Content:* Wall backfills classified as a silt or clay should in general not be used in seismically active areas.
- *Structures and Foundations within the Wall Active Zone:* The effect of these structures and foundations on the wall seismic loading shall be evaluated and the wall designed to take the additional load.
- *Protrusions through the Wall Face:* The additional seismic force transmitted to the wall, especially the facing, through the protruding structure (e.g., a culvert or drainage pipe) shall be evaluated. The effect of differential deformation between the protrusion and the wall face shall also be considered. Forces transmitted to the wall face by the protruding structure should be reduced through the use of compressible joint filler or bearing pads and sealant.

### C11.6.5.6

These recommended details are based on previous experiences with walls in earthquakes (e.g., Yen et al., 2011). Walls that did not utilize these details tended to have a higher frequency of problems than walls that did utilize these details.

With regard to preventing joints from opening up during shaking, this can be addressed through use of a backup panel placed behind the joint, a slip joint cover placed in front of the joint, or the placement of the geotextile strip behind the facing panels to bridge across the joint. The special units should allow differential vertical movement between facing units to occur while maintaining the functionality of the joint. The amount of overlap between these joint elements and the adjacent facing units is determined based on the amount of relative movement between facing units that is anticipated in much the same way that the bridge seat width is determined for bridges.

Little guidance on the amount of overlap between the backing panel and the facing panels is available for walls but past practice has been to provide a minimum overlap of 2.0 to 4.0 in. A geotextile strip may also be placed between the backfill soil and the joint or joint and backing panel combination. Typical practice has been to use a minimum overlap of the geotextile beyond the edges of the joint of 6.0 to 9.0 in. and the geotextile is usually attached to the back of the panel using adhesive. Typically, a Class 1 or Class 2 high elongation (>50 percent strain at peak strength) drainage geotextile in accordance with AASHTO M 288 is used. Similarly, this technique may be applied to the joint between the facing units and protrusions through the wall facing.

For wall corners, not cast monolithically, a special facing unit formed to go across the corner should be used to provide continuity and stability across a continuous corner vertical joint. Historically, corners and abrupt alignment changes in walls have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This should be considered when designing and detailing a wall corner for seismic loading. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

Note that the corner or abrupt alignment change enclosed angle as defined in the previous paragraph can either be internal or external to the wall.

With regard to wall backfill materials, walls that have used compacted backfills with high silt or clay content have historically exhibited more performance problems during earthquakes than those that have utilized compacted granular backfills. This has especially been an issue if the wall backfill does not have adequate drainage

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

features to keep water out of the backfill and the backfill fully drained. Also, very uniform clean sand backfill, especially if it lacks angularity, has also been problematic with regard to wall seismic performance. The issue is how well it can be compacted and remain in a compacted state. A backfill soil coefficient of uniformity of greater than 4 is recommended and, in general, the backfill particles should be classified as subangular or angular rather than rounded or subrounded. The less angular the backfill particles, the more well graded the backfill material needs to be.

For additional information on good wall details, see Berg et al. (2009). While this reference is focused on MSE wall details, similar details could be adapted for gravity and semigravity walls.

### 11.6.6—Drainage

Backfills behind abutments and retaining walls shall be drained or, if drainage cannot be provided, the abutment or wall shall be designed for loads due to earth pressure, plus full hydrostatic pressure due to water in the backfill.

### C11.6.6

Weep holes or geocomposite panel drains at the wall face do not assure fully drained conditions. Drainage systems should be designed to completely drain the entire retained soil volume behind the retaining wall face.

## 11.7—PIERS

### 11.7.1—Load Effects in Piers

Piers shall be designed to transmit the loads on the superstructure, and the loads acting on the pier itself, onto the foundation. The loads and load combinations shall be as specified in Section 3.

The structural design of piers shall be in accordance with the provisions of Sections 5, 6, 7, and 8, as appropriate.

### 11.7.2—Pier Protection

#### 11.7.2.1—Collision

Where the possibility of collision exists from highway or river traffic, an appropriate risk analysis should be made to determine the degree of impact resistance to be provided and/or the appropriate protection system. Collision loads shall be determined as specified in Articles 3.6.5 and 3.14.

#### 11.7.2.2—Collision Walls

Collision walls may be required by railroad owners if the pier is in close proximity to the railroad.

#### C11.7.2.2

Collision walls are usually required by the railroad owner if the column is within 25.0 ft of the rail. Some railroad owners require a collision wall 6.5 ft above the top of the rail between columns for railroad overpasses.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 11.7.2.3—Scour

The scour potential shall be determined and the design shall be developed to minimize failure from this condition as specified in Article 2.6.4.4.2.

#### 11.7.2.4—Facing

Where appropriate, the pier nose should be designed to effectively break up or deflect floating ice or drift.

#### C11.7.2.4

In these situations, pier life can be extended by facing the nosing with steel plates or angles, and by facing the pier with granite.

## 11.8—NONGRAVITY CANTILEVERED WALLS

### 11.8.1—General

Nongravity cantilevered walls may be considered for temporary and permanent support of stable and unstable soil and rock masses. The feasibility of using a nongravity cantilevered wall at a particular location shall be based on the suitability of soil and rock conditions within the depth of vertical element embedment to support the wall.

#### C11.8.1

Depending on soil conditions, nongravity cantilevered walls less than about 15.0 ft in height are usually feasible, with the exception of cylinder or tangent pile walls, where greater heights can be used.

### 11.8.2—Loading

The provisions of Article 11.6.1.2 shall apply. The load factor for lateral earth pressure, *EH*, shall be applied to the lateral earth pressures for the design of nongravity cantilevered walls.

#### C11.8.2

Lateral earth pressure distributions for design of nongravity cantilevered walls are provided in Article 3.11.5.6.

### 11.8.3—Movement at the Service Limit State

#### 11.8.3.1—Movement

The provisions of Articles 10.7.2.2 and 10.8.2.1 shall apply. The effects of wall movements on adjacent facilities shall be considered in the selection of the design earth pressures in accordance with the provisions of Article 3.11.1.

#### C11.8.3.1

Table C3.11.1-1 provides approximate magnitudes of relative movements required to achieve active earth pressure conditions in the retained soil and passive earth pressure conditions in the resisting soil.

### 11.8.4—Safety against Soil Failure at the Strength Limit State

#### 11.8.4.1—Overall Stability

The provisions of Article 11.6.3.7 shall apply.

#### C11.8.4.1

Discrete vertical elements penetrating across deep failure planes can provide resistance against failure. The magnitude of resistance will depend on the size, type, and spacing of vertical elements. Use of vertical wall elements to provide resistance against overall stability failure is described in Article C11.9.4.4.

The provisions of Article 11.6.3.5 shall apply.

Vertical elements shall be designed to support the full design earth, surcharge, and water pressures between the elements. In determining the embedment depth to mobilize passive resistance, consideration shall be given to planes of weakness, e.g., slickensides, bedding planes, and joint sets that could reduce the strength of the soil or rock determined by field or laboratory tests. Embedment in intact rock, including massive to appreciably jointed rock which

The maximum spacing between vertical supporting elements depends on the relative stiffness of the vertical elements. Spans of 6.0 to 10.0 ft are typical, depending on the type and size of facing.

In determining the embedment depth of vertical wall elements, consideration should be given to the presence of planes of weakness in the soil or rock that could result in a reduction of passive resistance. For laminated, jointed, or fractured soils and rocks, the residual strength along planes

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

should not fail through a joint surface, shall be based on the shear strength of the rock mass.

of weakness should be considered in the design and, where the planes are oriented at other than an angle of (45 degrees − $\phi'_f/2$) from the horizontal in soil or 45 degrees from the horizontal in rock toward the excavation, the orientation of the planes should also be considered. Where the wall is located on a bench above a deeper excavation, consideration should be given to the potential for bearing failure of a supporting wedge of soil or rock through intact materials along planes of weakness.

In designing permanent nongravity cantilevered walls with continuous vertical elements embedded in granular soil, the simplified earth pressure distributions in Figure 3.11.5.6-3 may be used with the following simplified design procedure (Teng, 1962):

- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads, and differential water pressure over the design height of the wall using $k_{a1}$.
- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads, and differential water pressure over the design height of the wall using $k_{a2}$.
- Determine in the following equation the value $x$ as defined in Figure 3.11.5.6-3 to determine the distribution of net passive pressure in front of the wall below the design height:

$$x = \left[\gamma k_{a2}\gamma'_{s1}H\right] / \left[\left(\phi k_{p2} - \gamma k_{a2}\right)\gamma'_{s2}\right] \qquad \text{(C11.8.4.1-1)}$$

where:

$\gamma$ = load factor for horizontal earth pressure, $EH$ (dim.)
$k_{a2}$ = the active earth pressure coefficient for soil 2 (dim.)
$\gamma'_{s1}$ = the effective soil unit weight for soil 1 (kcf)
$H$ = the design height of the wall (ft)
$\phi$ = the resistance factor for passive resistance in front of the wall (dim.)
$k_{p2}$ = the passive earth pressure coefficient for soil 2 (dim.)
$\gamma'_{s2}$ = the effective soil unit weight for soil 2 (kcf)

- Sum moments about the point of action of $F$ (the base of the wall) to determine the embedment, $D_o$, for which the net passive pressure is sufficient to provide moment equilibrium.
- Determine the depth at which the shear in the wall is zero, i.e., the point at which the areas of the driving and resisting pressure diagrams are equivalent.
- Calculate the maximum bending moment at the point of zero shear.
- Calculate the design depth, $D = 1.2D_o$, to account for errors inherent in the simplified passive pressure distribution.

For design of temporary, nongravity cantilevered walls with continuous vertical elements embedded in cohesive soil, an approach similar to the simplified

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

method for continuous vertical elements embedded in granular soil may be applied considering the earth pressure distributions shown in Figures 3.11.5.6-6 and 3.11.5.6-7 (Teng, 1962).

## 11.8.5—Safety against Structural Failure

### 11.8.5.1—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, and earthquake loadings.

### C11.8.5.1

Discrete vertical wall elements include driven piles, drilled shafts, and auger-cast piles, e.g., piles and built-up sections installed in preaugered holes.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent drilled shafts.

The maximum bending moments and shears in vertical wall elements may be determined using the loading diagrams in Article 3.11.5.6, and appropriate load and resistance factors.

### 11.8.5.2—Facing

The maximum spacing between discrete vertical wall elements shall be determined based on the relative stiffness of the vertical elements and facing, the type and condition of soil to be supported, and the type and condition of the soil in which the vertical wall elements are embedded. Facing may be designed assuming simple support between elements, with or without soil arching, or assuming continuous support over several elements.

If timber facing is used, it shall be stress-grade pressure-treated lumber in conformance with Section 8. If timber is used where conditions are favorable for the growth of decay-producing organisms, wood should be pressure-treated with a wood preservative unless the heartwood of a naturally decay-resistant species is available and is considered adequate with respect to the decay hazard and expected service life of the structure.

### C11.8.5.2

In lieu of other suitable methods, for preliminary design the maximum bending moments in facing may be determined as follows:

- For simple spans without soil arching:

$$M_{max} = 0.125pL^2 \qquad \text{(C11.8.5.2-1)}$$

- For simple spans with soil arching:

$$M_{max} = 0.083pL^2 \qquad \text{(C11.8.5.2-2)}$$

- For continuous spans without soil arching:

$$M_{max} = 0.1pL^2 \qquad \text{(C11.8.5.2-3)}$$

- For continuous spans with soil arching:

$$M_{max} = 0.083pL^2 \qquad \text{(C11.8.5.2-4)}$$

where:

$M_{max}$ = factored flexural moment on a unit width or height of facing (kip-ft/ft)
$p$ = average factored lateral pressure, including earth, surcharge, and water pressure acting on the section of facing being considered (ksf/ft)
$L$ = spacing between vertical elements or other facing supports (ft)

If the variations in lateral pressure with depth are large, moment diagrams should be constructed to provide

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

more accuracy. The facing design may be varied with depth.

Eq. C11.8.5.2-1 is applicable for simply supported facing behind which the soil will not arch between vertical supports, e.g., in soft cohesive soils or for rigid concrete facing placed tightly against the in-place soil. Eq. C11.8.5.2-2 is applicable for simply supported facing behind which the soil will arch between vertical supports, e.g., in granular or stiff cohesive soils with flexible facing or rigid facing behind which there is sufficient space to permit the in-place soil to arch. Eqs. C11.8.5.2-3 and C11.8.5.2-4 are applicable for facing which is continuous over several vertical supports, e.g., reinforced shotcrete or concrete.

## 11.8.6—Seismic Design of Nongravity Cantilever Walls

### 11.8.6.1—General

The effect of earthquake loading shall be investigated using the Extreme Event I limit state of Table 3.4.1-1 with resistance factor $\phi = 1.0$, a load factor $\gamma_p = 1.0$ and an accepted methodology, with the exception of overall stability of the wall, in which case a resistance factor of 0.9 and a load factor $\gamma_p = 1.0$ should be used as specified in Articles 3.4.1 and 11.5.8.

The seismic analysis of the nongravity cantilever retaining wall shall demonstrate that the cantilever wall will maintain overall stability and withstand the seismic earth pressures induced by the design earthquake without excessive structural moments and shear on the cantilever wall section. Limit equilibrium methods or numerical displacement analyses shall be used to confirm acceptable wall performance.

Design checks should also be performed for failures below the excavation level but through the structure. These analyses should include the contributions of the structural section to slope stability. If the structural contribution to resistance is being accounted for in the stability assessment, the moments and shears developed by the structural section should be checked to confirm that specified structural limits are not exceeded.

### C11.8.6.1

During seismic loading, the nongravity cantilever wall develops resistance to load through the passive resistance of the soil below the excavation depth. The stiffness of the structural wall section above the excavation depth must be sufficient to transfer seismic forces from the soil behind the wall, through the structural section, to the soil below. The seismic evaluation of the nongravity cantilever wall requires, therefore, determination of the demand on the wall from the seismic active earth pressure and the capacity of the soil from the seismic passive soil resistance.

For flexible cantilevered walls, forces resulting from wall inertia effects may be ignored in estimating the seismic design forces. However, for very massive nongravity cantilever wall systems, such as tangent or secant pile walls, wall mass inertia effects should be included in the seismic analysis of the wall.

Two types of stability checks are conducted for the nongravity cantilever wall: global stability and internal stability. In contrast to gravity and semigravity walls, sliding, overturning, and bearing stability are not design considerations for this wall type. By sizing the wall to meet earth pressures, the equilibrium requirements for external stability are also satisfied.

The global stability check for seismic loading involves a general slope failure analysis that extends below the base of the wall. Typically, the embedment depth of the wall is 1.5 to 2 times the wall height above the excavation level. For these depths, global stability is not normally a concern, except where soft layers are present below the toe of the wall.

The global stability analysis is performed with a slope stability program. The failure surfaces used in the analysis should normally extend below the depth of the structure member.

Internal stability for a nongravity cantilever wall refers to the moments and shear forces developed in the wall from the seismic loads.

### 11.8.6.2—Seismic Active Lateral Earth Pressure

Lateral earth pressures and inertial forces for seismic design of nongravity cantilever walls shall be determined as specified in Article 11.6.5. The resulting active seismic earth pressure shall be distributed as specified in Article 11.6.5.3, above the excavation level as shown in Figure 11.8.6.2-1.

To reduce the lateral seismic acceleration coefficient, $k_{h0}$, for the effects of horizontal wall displacement in accordance with Article 11.6.5.2.2, analyses shall demonstrate that the displacements associated with the yield acceleration do not result in any of the following:

- Yield of structural members making up the wall, such as with a pile-supported wall;
- Loads applied to the lateral support systems (e.g., ground anchors in anchored wall systems; see Article 11.9.6) that exceed the available factored resistance; and
- Unacceptable deformation or damage to any facilities located in the vicinity of the wall.

### C11.8.6.2

In most situations, the nongravity cantilever wall moves enough during seismic loading to develop seismic active earth pressures; however, the amount of movement may not be the 1.0 to 2.0 in. necessary to allow reduction in the seismic coefficient by 50 percent, unless analyses demonstrate that permanent wall movements will occur without damaging the wall components. Beam-column analyses involving *p-y* modeling of the vertical wall elements will usually be required to make this assessment.

If the effect of cohesion in reducing the seismic active earth pressure acting on the wall is considered, the reduction in earth pressure due to cohesion should not be combined with a reduction in earth pressure due to horizontal wall displacement.

As described in Article 11.6.5.3, an alternate approach for determining the seismic active earth pressure involves use of the generalized limit equilibrium method. If used for the design of a nongravity cantilever wall, the geometry of the slope stability model should extend from the ground surface to the bottom or toe of the sheet pile or other nongravity cantilever walls in which the wall is continuous both above and below the excavation line in front of the wall. For soldier pile walls, the analysis extends to the excavation level. The seismic active pressure is determined as described in Appendix A11.

The static lateral earth pressure force acting behind the wall is already included in $P_{AE}$ (i.e., $P_{AE}$ is the combination of the static and seismic lateral earth pressure). See Articles 3.11.6.3 and 11.10.10.1 for definition of terms in Figure 11.8.6.2-1 not specifically defined in this Article.

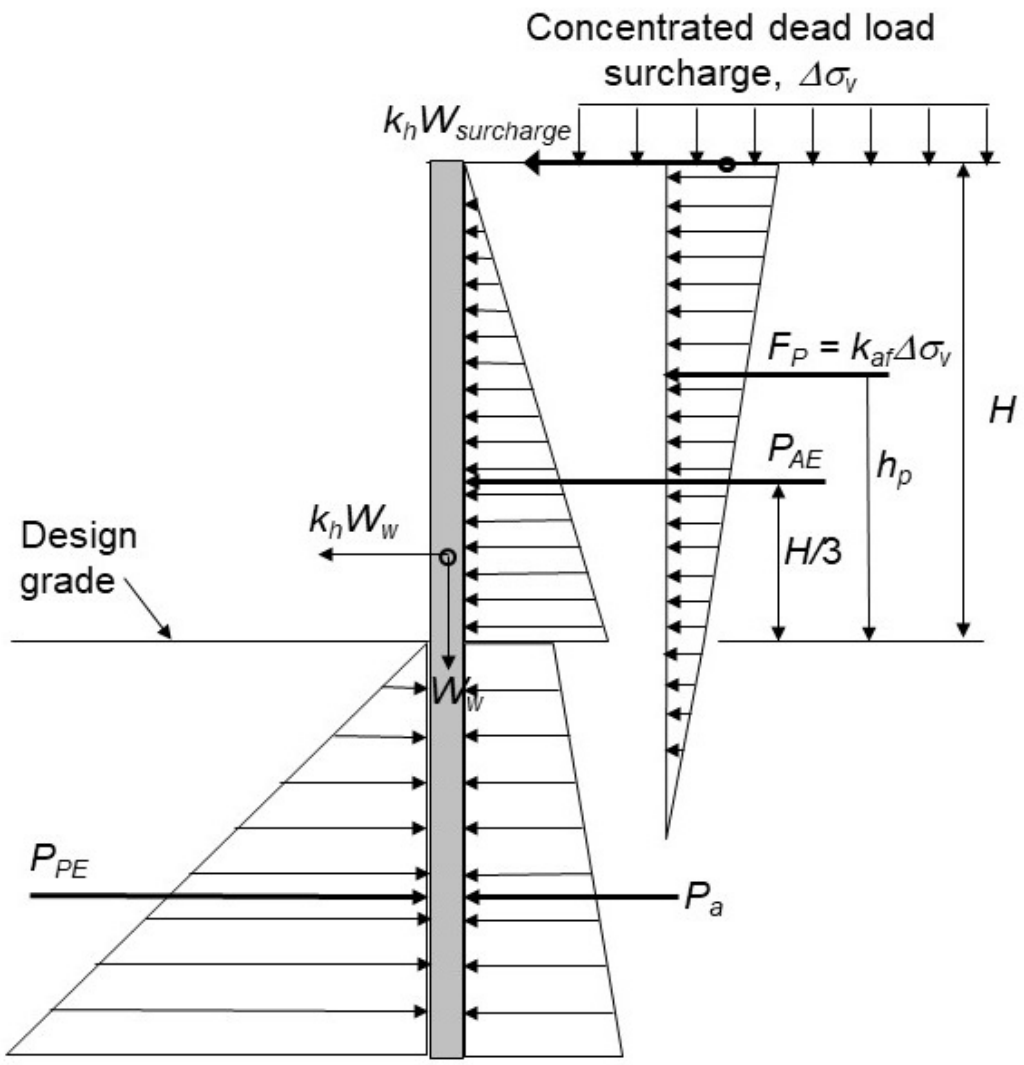

**Figure 11.8.6.2-1—Seismic Force Diagram for Nongravity Cantilever Wall External Stability Evaluation**

### 11.8.6.3—Seismic Passive Lateral Earth Pressure

The method used to compute the seismic passive pressure shall consider wall interface friction, the nonlinear failure surface that develops during passive pressure loading, and the inertial response of the soil within the passive pressure wedge for depths greater than 5.0 ft. Cohesion and frictional properties of the soil shall be included in the determination. Passive pressure under seismic loading shall be determined as specified in Article 11.6.5.5.

In the absence of any specific guidance or research results for seismic loading, a wall interface friction equal to two-thirds of the soil friction angle should be used when calculating seismic passive pressures.

### C11.8.6.3

The effects of live loads are usually neglected in the computation of seismic passive pressure.

Reductions in the seismic passive earth pressure may be warranted to limit the amount of deformation required to mobilize the seismic passive earth pressure, if a limit equilibrium method of analysis is used, to make sure that the wall movement does not result in the collapse of the wall or of structures directly supported by the wall. However, a passive resistance reduction factor near 1.0 may be considered if, in the judgment of the engineer, such deformations to mobilize the passive resistance would not result in wall or supported structure collapse.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The seismic passive pressure shall be applied as a triangular pressure distribution similar to that for static loading. The amount of displacement to mobilize the passive pressure shall also be considered in the analyses.

The peak seismic passive pressure should be based on:

- the time-averaged mean groundwater elevation,
- the full depth of the below-ground structural element, not neglecting the upper 2.0 ft of soil as typically done for static analyses,
- the strength of the soil for undrained loading, and
- the wall friction in the passive pressure estimate taken as two-thirds times the soil strength parameters from a total stress analysis.

In the absence of specific guidance for seismic loading, a reduction factor of 0.67 should be applied to the seismic passive pressure during the seismic check to limit displacement required to mobilize the passive earth pressure.

If the nongravity cantilever wall uses soldier piles to develop reaction to active pressures, adjustments must be made in the passive earth pressure determination to account for the three-dimensional effects below the excavation level as soil reactions are developed. In the absence of specific seismic studies dealing with this issue, it is suggested that methods used for static loading be adopted. One such method, documented in the California Department of Transportation (Caltrans) *Shoring Manual* (2010), suggests that soldier piles located closer than three pile diameters be treated as a continuous wall. For soldier piles spaced at greater distances, the approach in the *Shoring Manual* depends on the type of soil:

- For cohesive soils, the effective pile width that accounts for arching ranges from one pile diameter for very soft soil to two diameters for stiff soils.
- For cohesionless soils, the effective width is defined as $0.08\phi B$ up to three pile diameters. In this relationship, $\phi$ is the soil friction angle and $B$ is the soldier pile width.

During seismic loading, the inertial response of the soil within the passive pressure failure wedge will decrease the soil resistance during a portion of each loading cycle. Figures provided in Appendix A11 can be used to estimate the passive soil resistance for different friction values and normalized values of cohesion. A preferred methodology for computing seismic earth pressures with consideration of wall friction, nonlinear soil failure surface, and inertial effects involves use of the procedures documented by Shamsabadi et al. (2007).

**11.8.6.4—Wall Displacement Analyses to Determine Earth Pressures**

Numerical displacement analyses, if used, shall show that moments, shear forces, and structural displacements resulting from the peak ground surface accelerations are within acceptable levels. These analyses shall be conducted using a model of the wall system that includes the structural stiffness of the wall section, as well as the load displacement response of the soil above and below the excavation level.

**C11.8.6.4**

Numerical displacement methods offer a more accurate and preferred method of determining the response of nongravity cantilever walls during seismic loading. Either of two numerical approaches can be used. One involves a simple beam-column approach; the second involves the use of a two-dimensional computer model. Both approaches need to appropriately represent the load displacement behavior of the soil and the structural members during loading. For soils, this includes nonlinear stress–strain effects; for structural members, consideration must be given to ductility of the structure, including the use of cracked versus uncracked section properties if concrete structures are being used.

All rights reserved. Duplication is a violation of applicable law.

*Beam-Column Approach*

The pseudostatic seismic response of a nongravity cantilever wall can be determined by representing the wall in a beam-column model with the soil characterized by *p-y* springs. This approach is available with commercially available computer software. The total seismic active pressure above the excavation level is used for wall loading. Procedures given in Article 11.8.6.2 should be used to make this estimate.

For this approach, the *p-y* curves below the excavation level need to be specified. For discrete structural elements (e.g., soldier piles), conventional *p-y* curves for piles may be used. For continuous walls or walls with pile elements at closer than 3 diameter spacing, *p*- and *y*-modifiers have been developed by Anderson et al. (2008) to represent a continuous (sheet pile or secant pile) retaining wall. The procedure involves:

- Developing conventional isolated pile *p-y* curves using a 4.0-ft diameter pile following API (1993) procedures for sands or clays.
- Normalizing the isolated *p-y* curves by dividing the *p* values by 4.0 ft.
- Applying the following *p*- and *y*-multipliers, depending on the type of soil, in a conventional beam-column analysis.

| Soil Type | *p*-multiplier | *y*-multiplier |
|---|---|---|
| Sand | 0.5 | 4.0 |
| Clay | 1.0 | 4.0 |

It should be noted that the starting point of using a 4.0 ft diameter pile has nothing to do with the actual diameter of the vertical elements in the wall. It is simply a starting point in the procedure to obtain *p-y* curves that are applicable to a wall. The *p-y* curves obtained in the final step of this process are intended to be applicable to a continuous wall.

Supporting information for the development and use of the *p-y* approach identified above is presented in Volume 1 of NCHRP 611 Report (Anderson et al., 2008). The earth pressure used as the load in the beam column analysis is determined from one of the limit equilibrium methods, including M–O with or without cohesion or the generalized limit equilibrium procedure, as discussed in Article 11.6.5. The benefit of the *p-y* approach is that it enforces compatibility of deflections, earth pressure, and flexibility of the wall system. The method is in contrast to the limit equilibrium method in which the effects of the wall flexibilities are ignored. This is very important for the seismic design and performance of the wall during seismic event. The deformation and rotation of the wall can easily be captured using the *p-y* approach.

All rights reserved. Duplication is a violation of applicable law.

*Finite Difference or Finite Element Modeling*

Pseudostatic or dynamic finite element or finite difference procedures in computer programs can also be used to evaluate the seismic response of nongravity cantilever walls during seismic loading. For two-dimensional models, it may be necessary to "smear" the stiffness of the structural section below the excavation level to adjust the model to an equivalent two-dimensional representation if the below-grade portion of the wall is formed from discrete piles (e.g., soldier piles).

The finite difference or finite element approach to evaluating wall response will involve a number of important assumptions; therefore, this approach should be discussed with and agreed to by the Owner before being adopted. As part of the discussions, the possible limitations and the assumptions being made for the model should be reviewed.

**11.8.7—Corrosion Protection**

The level and extent of corrosion protection shall be a function of the ground environment and the potential consequences of a wall failure.

**C11.8.7**

Corrosion protection for piles and miscellaneous hardware and material should be consistent with the design life of the structure.

**11.8.8—Drainage**

The provisions of Article 3.11.3 shall apply.

Seepage shall be controlled by installation of a drainage medium behind the facing with outlets at or near the base of the wall. Drainage panels shall maintain their drainage characteristics under the design earth pressures and surcharge loadings, and shall extend from the base of the wall to a level 1.0 ft below the top of the wall.

Where thin drainage panels are used behind walls, and saturated or moist soil behind the panels may be subjected to freezing and expansion, either insulation shall be provided on the walls to prevent freezing of the soil, or the wall shall be designed for the pressures exerted on the wall by frozen soil.

**C11.8.8**

In general, the potential for development of hydrostatic pressures behind walls with discrete vertical elements and lagging is limited due to the presence of openings in the lagging, and the disturbance of soil behind lagging as the wall is constructed. However, the potential for leakage through the wall should not be counted upon where the ground water level exceeds one-third the height of the wall because of the potential for plugging and clogging of openings in the wall with time by migration of soil fines. It is probable that, under such conditions, a wall with continuous vertical elements, i.e., a cutoff wall constructed with a drainage system designed to handle anticipated flows, will be required.

Water pressures may be considered reduced in design only if positive drainage, e.g., drainage blanket, geocomposite drainage panels, gravel drains with outlet pipes, is provided to prevent buildup of hydrostatic pressure behind the wall. Thin drains at the back of the wall face may not completely relieve hydrostatic pressure and may increase seepage forces on the back of the wall face due to rainwater infiltration, Terzaghi and Peck (1967) and Cedergren (1989). The effectiveness of drainage control measures should be evaluated by seepage analyses.

**11.9—ANCHORED WALLS**

**11.9.1—General**

Anchored walls, whose elements may be proprietary, employ grouted in anchor elements, vertical wall

**C11.9.1**

Depending on soil conditions, anchors are usually required for support of both temporary and permanent

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

elements, and facing. Anchored walls, illustrated in Figure 11.9.1-1, may be considered for both temporary and permanent support of stable and unstable soil and rock masses.

The feasibility of using an anchored wall at a particular location should be based on the suitability of subsurface soil and rock conditions within the bonded anchor stressing zone.

Where fill is placed behind a wall, either around or above the unbonded length, special designs and construction specifications shall be provided to prevent anchor damage.

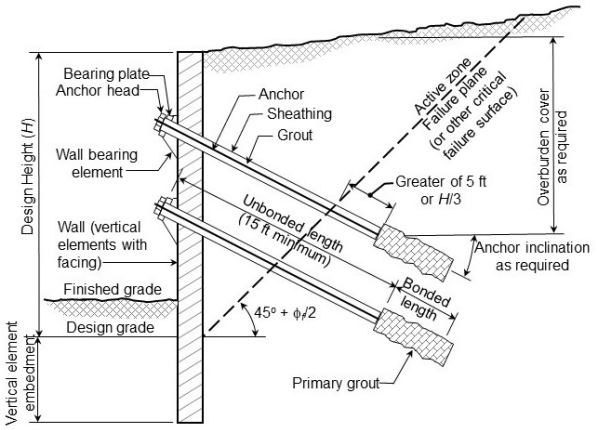

**Figure 11.9.1-1—Anchored Wall Nomenclature and Anchor Embedment Guidelines**

### 11.9.2—Loading

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered.

### 11.9.3—Movement at the Service Limit State

#### 11.9.3.1—Movement

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply.

The effects of wall movements on adjacent facilities shall be considered in the development of the wall design.

nongravity cantilevered walls higher than about 10.0 to 15.0 ft.

The availability or ability to obtain underground easements and proximity of buried facilities to anchor locations should also be considered in assessing feasibility.

Anchored walls in cuts are typically constructed from the top of the wall down to the base of the wall. Anchored walls in fill must include provisions to protect against anchor damage resulting from backfill and subsoil settlement or backfill and compaction activities above the anchors.

The minimum distance between the front of the bond zone and the active zone behind the wall of 5.0 ft or $H/5$ is needed to ensure that no load from the bonded zone is transferred into the no load zone due to load transfer through the grout column in the no load zone.

### C11.9.2

Lateral earth pressures on anchored walls are a function of the rigidity of the wall-anchor system, soil conditions, method and sequence of construction, and level of prestress imposed by the anchors. Apparent earth pressure diagrams that are commonly used can be found in Article 3.11.5.7 and Sabatini et al. (1999).

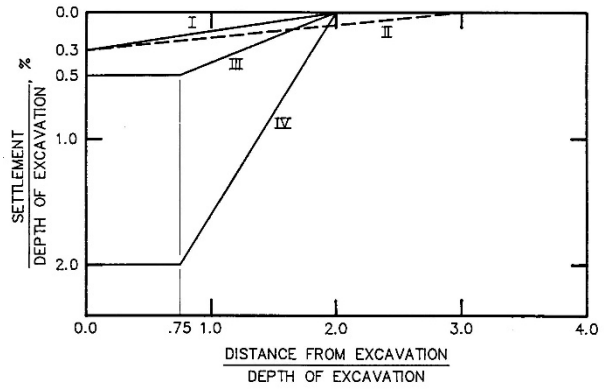
### C11.9.3.1

Settlement of vertical wall elements can cause reduction of anchor loads, and should be considered in design.

The settlement profiles in Figure C11.9.3.1-1 were recommended by Clough and O′Rourke (1990) to estimate ground surface settlements adjacent to braced or anchored excavations caused during the excavation and bracing stages of construction. Significant settlements may also be caused by other construction activities, e.g., dewatering or deep foundation construction within the

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

excavation, or by poor construction techniques, e.g., soldier pile, lagging, or anchor installation. The field measurements used to develop Figure C11.9.3.1-1 were screened by the authors to not include movements caused by other construction activities or poor construction techniques. Therefore, such movements should be estimated separately.



Where noted in the definition of the various curves in Figure C11.9.3.1-1, the basal heave ratio, $R_{BH}$, shall be taken as:

$$R_{BH} = \frac{5.1 S_u}{\gamma_s H + q_s} \qquad \text{(C11.9.3.1-1)}$$

where:

$S_u$ = undrained shear strength of cohesive soil (ksf)
$\gamma_s$ = unit weight of soil (kcf)
$H$ = height of wall (ft)
$q_s$ = surcharge pressure (ksf)

See Sabatini et al. (1999) for additional information on the effect of anchored wall construction and design on wall movement.

Curve I = Sand
Curve II = Stiff to very hard clay
Curve III = Soft to medium clay, $R_{BH} = 2.0$
Curve IV = Soft to medium clay, $R_{BH} = 1.2$

**Figure C11.9.3.1-1—Settlement Profiles behind Braced or Anchored Walls (adapted from Clough and O'Rourke, 1990)**

## 11.9.4—Safety against Soil Failure

### 11.9.4.1—Bearing Resistance

The provisions of Articles 10.6.3, 10.7.3, and 10.8.3 shall apply.

Bearing resistance shall be determined assuming that all vertical components of loads are transferred to the embedded section of the vertical wall elements.

### C11.9.4.1

For drilled in place vertical wall elements, e.g., drilled-in soldier piles, in sands, if the β-method is used to calculate the skin friction capacity, the depth, *z,* should be referenced to the top of the wall. The vertical overburden stress, $\sigma_v'$, however, should be calculated with reference to the elevation of the midheight of the exposed

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 11.9.4.2—Anchor Pullout Capacity

Prestressed anchors shall be designed to resist pullout of the bonded length in soil or rock. The factored pullout resistance of a straight shaft anchor in soil or rock, $Q_R$, is determined as:

$$Q_R = \phi Q_n = \phi \pi D_{DH} \tau_a L_b \quad (11.9.4.2\text{-}1)$$

where:

$\phi$ = resistance factor for anchor pullout (dim.)
$Q_n$ = nominal anchor pullout resistance (kips)
$D_{DH}$ = diameter of anchor drill hole (ft)
$\tau_n$ = nominal anchor bond stress (ksf)
$L_b$ = anchor bond length (ft)

For preliminary design, the resistance of anchors may either be based on the results of anchor pullout load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing, and previous experience; or estimated using published soil/rock–grout bond guidelines. For final design, the contract documents may require preproduction tests such as pullout tests or extended creep tests on sacrificial anchors be conducted to establish anchor lengths and capacities that are consistent with the contractor′s chosen method of anchor installation. Either performance or proof tests shall be conducted on every production anchor to 1.0 or greater times the factored load to verify capacity.

wall, with $\beta$ and $\sigma_v'$ evaluated at the midpoint of each soil layer.

### C11.9.4.2

Anchor pullout capacity is influenced by soil and rock conditions, method of anchor hole advancement, hole diameter, bonded length, grout type, and grouting pressure. Information on anchor pullout capacity may be found in Sabatini et al. (1999), PTI (1996), Cheney (1984), and Weatherby (1982). As a guide, the presumptive values provided in Tables C11.9.4.2-1, C11.9.4.2-2, and C11.9.4.2-3 may be used to estimate the nominal (ultimate) bond for small diameter anchors installed in cohesive soils, cohesionless soils, and rock, respectively. It should be recognized that the values provided in the tables may be conservative.

**Table C11.9.4.2-1—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesive Soils**

| Anchor/Soil Type (Grout Pressure) | Soil Stiffness or Unconfined Compressive Strength (tsf) | Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf) |
|---|---|---|
| Gravity Grouted Anchors (<50 psi) | | |
| Silt–Clay Mixtures | Stiff to Very Stiff 1.0–4.0 | 0.6 to 1.5 |
| Pressure Grouted Anchors (50 psi–400 psi) | | |
| High Plasticity Clay | Stiff 1.0–2.5<br>V. Stiff 2.5–4.0 | 0.6 to 2<br>1.5 to 3.6 |
| Medium Plasticity Clay | Stiff 1.0–2.5<br>V. Stiff 2.5–4.0 | 2.0 to 5.2<br>2.9 to 7.3 |
| Medium Plasticity Sandy Silt | V. Stiff 2.5–4.0 | 5.8 to 7.9 |

**Table C11.9.4.2-2—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesionless Soils**

| Anchor/Soil Type (Grout Pressure) | Soil Compactness or *SPT* Resistance[a] | Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf) |
|---|---|---|
| Gravity Grouted Anchors (<50 psi) | | |
| Sand or Sand–Gravel Mixtures | Medium Dense to Dense 11–50 | 1.5 to 2.9 |
| Pressure Grouted Anchors (50 psi–400 psi) | | |
| Fine to Medium Sand | Medium Dense to Dense 11–50 | 1.7 to 7.9 |
| Medium to Coarse Sand w/ Gravel | Medium Dense 11–30 | 2.3 to 14 |
| | Dense to Very Dense 30–50 | 5.2 to 20 |
| Silty Sands | — | 3.5 to 8.5 |
| Sandy Gravel | Medium Dense to Dense 11–40 | 4.4 to 29 |
| | Dense to Very Dense 40–50+ | 5.8 to 29 |
| Glacial Till | Dense 31–50 | 6.3 to 11 |

[a] Corrected for overburden pressure.

**Table C11.9.4.2-3—Presumptive Ultimate Unit Bond Stress for Anchors in Rock**

| Rock Type | Presumptive Ultimate Unit Bond Stress, $\tau_n$ (ksf) |
|---|---|
| Granite or Basalt | 36 to 65 |
| Dolomitic Limestone | 29 to 44 |
| Soft Limestone | 21 to 29 |
| Slates & Hard Shales | 17 to 29 |
| Sandstones | 17 to 36 |
| Weathered Sandstones | 15 to 17 |
| Soft Shales | 4.2 to 17 |

The presumptive ultimate anchor bond stress values presented in Tables C11.9.4.2-1 through C11.9.4.2-3 are intended for preliminary design or evaluation of the feasibility of straight shaft anchors installed in small diameter holes. Pressure-grouted anchors may achieve much higher capacities. The total capacity of a pressure-grouted anchor may exceed 500 kips in soil or 2000 to 3000 kips in rock, although such high capacity anchors are seldom used for highway applications. Post-grouting can also increase the load carrying capacity of straight shaft anchors by 20–50 percent or more per phase of post-grouting.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The anchor load shall be developed by suitable embedment outside of the critical failure surface in the retained soil mass.

Determination of the unbonded anchor length, inclination, and overburden cover shall consider:

- The location of the critical failure surface furthest from the wall,

The resistance factors in Table 11.5.7-1, in combination with the load factor for horizontal active earth pressure (Table 3.4.1-2), are consistent with what would be required based on allowable stress design, for preliminary design of anchors for pullout (Sabatini et al., 1999). These resistance factors are also consistent with the results of statistical calibration of full-scale anchor pullout tests relative to the minimum values of presumptive ultimate unit bond stresses shown in Tables C11.9.4.2-1 through C11.9.4.2-3. Use of the resistance factors in Table 11.5.7-1 and the load factor for apparent earth pressure for anchor walls in Table 3.4.1-2, with values of presumptive ultimate unit bond stresses other than the minimum values in Tables C11.9.4.2-1 through C11.9.4.2-3 could result in unconservative designs unless the Engineer has previous experience with the particular soil or rock unit in which the bond zone will be established.

Presumptive bond stresses greater than the minimum values shown in Tables C11.9.4.2-1 through C11.9.4.2-3 should be used with caution, and be based on past successful local experience, such as a high percentage of passing proof tests in the specified or similar soil or rock unit at the design bond stress chosen, or anchor pullout test results in the specified or similar soil or rock unit. Furthermore, in some cases the specified range of presumptive bond stresses is representative of a range of soil conditions. Soil conditions at the upper end of the specified range, especially if coupled with previous experience with the particular soil unit, may be considered in the selection of anchor bond stresses above the minimum values shown. Selection of a presumptive bond stress for preliminary anchor sizing should consider the risk of failing proof tests if the selected bond stress was to be used for final design. The goal of preliminary anchor design is to reduce the risk of having a significant number of production anchors fail proof or performance tests as well as the risk of having to redesign the anchored wall to accommodate more anchors due to an inadequate easement behind the wall, should the anchor capacities predicted during preliminary design not be achievable. See Article 11.9.8.1 for guidance on anchor testing.

Significant increases in anchor capacity for anchor bond lengths greater than approximately 40.0 ft cannot be achieved unless specialized methods are used to transfer load from the top of the anchor bond zone towards the end of the anchor. This is especially critical for strain sensitive soils, in which residual soil strength is significantly lower than the peak soil strength.

Anchor inclination and spacing will be controlled by soil and rock conditions, the presence of geometric constraints and the required anchor capacity. For tremie-grouted anchors, a minimum angle of inclination of about 10 degrees and a minimum overburden cover of about 15.0 ft are typically required to assure grouting of the entire bonded length and to provide sufficient ground cover above the anchorage zone. For pressure-grouted anchors, the angle of inclination is generally not critical and is governed primarily by geometric constraints, and

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- The minimum length required to ensure minimal loss of anchor prestress due to long-term ground movements,
- The depth to adequate anchoring strata, as indicated in Figure 11.9.1-1, and
- The method of anchor installation and grouting.

The minimum horizontal spacing of anchors should be the larger of three times the diameter of the bonded zone, or 5.0 ft. If smaller spacings are required to develop the required load, consideration may be given to differing anchor inclinations between alternating anchors.

the minimum overburden cover is typically 6.0–15.0 ft. Steep inclinations may be required to avoid anchorage in unsuitable soil or rock. Special situations may require horizontal or near horizontal anchors, in which case proof of sufficient overburden and full grouting should be required.

The minimum horizontal spacing specified for anchors is intended to reduce stress overlap between adjacent anchors.

Anchors used for walls constructed in fill situations, i.e., bottom-up construction, should be enclosed in protective casing to prevent damage during backfill placement, compaction, and settlement.

Selection of anchor type depends on anticipated service life, soil and rock conditions, ground water level, subsurface environmental conditions, and method of construction.

#### 11.9.4.3—Passive Resistance

#### C11.9.4.3

The provisions of Articles 3.11.5.6, 11.6.3.5, 11.6.3.6, and 11.8.4.1 shall apply.

It is recommended in Sabatini et al. (1999) that methods such as the Broms Method or the Wang and Reese Method be used to evaluate passive resistance and the wall vertical element embedment depth needed. However, these methods have not been calibrated for this application for LRFD as yet.

If the effective width of the discrete vertical elements of the wall is increased to greater than the physical width of the vertical elements, the background regarding this issue as described in Article C3.11.5.6 applies.

#### 11.9.4.4—Overall Stability

#### C11.9.4.4

The provisions of Articles 3.4.1 and 11.6.3.7 shall apply.

Detailed guidance for evaluating the overall stability of anchored wall systems, including how to incorporate anchor forces in limit equilibrium slope stability analyses, is provided by Sabatini et al. (1999).

The effect of discrete vertical elements penetrating deep failure planes and acting as in-situ soil improvement may be negligible if the percentage of reinforcement provided by the vertical elements along the failure surface is small. However, it is possible to consider the effect of the discrete vertical elements by modeling the elements as a cohesion along the failure surface, or by evaluating the passive capacity of the elements.

### 11.9.5—Safety Against Structural Failure

#### 11.9.5.1—Anchors

#### C11.9.5.1

The horizontal component of anchor design force shall be computed using the provisions of Article 11.9.2 and any other horizontal pressure components acting on the wall in Article 3.11. The total anchor design force shall be determined based on the anchor inclination. The horizontal anchor spacing and anchor capacity shall be selected to provide the required total anchor design force.

Anchor tendons typically consist of steel bars, wires, or strands. The selection of anchor type is generally the responsibility of the contractor.

A number of suitable methods for the determination of anchor loads are in common use. Sabatini et al. (1999) provides two methods which can be used: the Tributary Area Method, and the Hinge Method. These methods are illustrated in Figures C11.9.5.1-1 and

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

C11.9.5.1-2. These figures assume that the soil below the base of the excavation has sufficient strength to resist the reaction force, *R*. If the soil providing passive resistance below the base of the excavation is weak and is inadequate to carry the reaction force, *R*, the lowest anchor should be designed to carry both the anchor load as shown in the figures as well as the reaction force. See Article 11.8.4.1 for evaluation of passive resistance. Alternatively, soil-structure interaction analyses, e.g., beam on elastic foundation, can be used to design continuous beams with small toe reactions, as it may be overly conservative to assume that all of the load is carried by the lowest anchor.

In no case should the maximum test load be less than the factored load for the anchor.

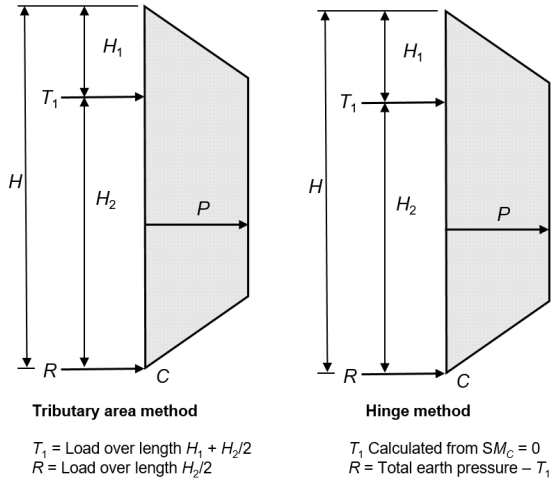

**Figure C11.9.5.1-1—Calculation of Anchor Loads for One-Level Wall after Sabatini et al. (1999)**

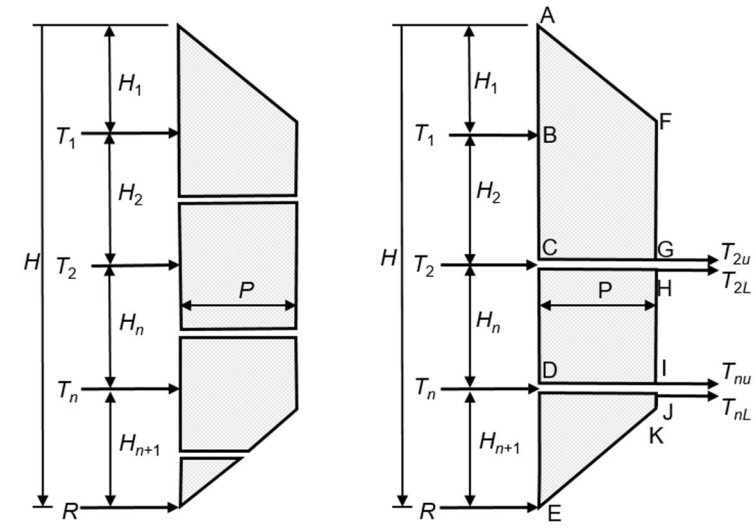

**Figure C11.9.5.1-2—Calculation of Anchor Loads for Multilevel Wall after Sabatini et al. (1999)**

### 11.9.5.2—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, anchor, and seismic loadings, as well as the vertical component of the anchor loads and any other vertical loads. Horizontal supports may be assumed at each anchor location and at the bottom of the excavation if the vertical element is sufficiently embedded below the bottom of the excavation.

### C11.9.5.2

Discrete vertical wall elements are continuous throughout their length and include driven piles, caissons, drilled shafts, and auger-cast piles, i.e., piles and built-up sections installed in preaugured holes and backfilled with structural concrete in the passive zone and lean concrete in the exposed section of the wall.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent caissons.

For structural analysis methods, see Section 4.

For walls supported in or through soft clays with $S_u < 0.15\gamma_s' H$, continuous vertical elements extending well below the exposed base of the wall may be required to prevent heave in front of the wall. Otherwise, the vertical elements are embedded approximately 3.0 ft or as required for stability or end bearing.

### 11.9.5.3—Facing

The provisions of Article 11.8.5.2 shall apply.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 11.9.6—Seismic Design

The provisions of Article 11.8.6 shall apply except as modified in this Article.

The seismic analysis of the anchored retaining wall shall demonstrate that the anchored wall can maintain overall stability and withstand the seismic earth pressures induced by the design earthquake without exceeding the capacity of the anchors or the structural wall section supporting the soil. Limit equilibrium methods or numerical displacement analyses shall be used to confirm acceptable wall performance.

Anchors shall be located behind the limit equilibrium failure surface for seismic loading. The location of the failure surface for seismic loading shall be established using methods that account for the seismic coefficient and the soil properties (i.e., $c$ and $\phi$) within the anchored zone.

### C11.9.6

See Article C11.8.6.

The seismic design of an anchored wall involves many of the same considerations as the nongravity cantilever wall. However, the addition of one or more anchors to the wall introduces some important differences in the seismic design check as identified in this Article.

The earth pressures above the excavation level result from the inertial response of the soil mass behind the wall. In contrast to a nongravity cantilever wall, the soil mass includes anchors that have been tensioned to minimize wall deflections under static earth pressures. During seismic loading, the bars or strands making up the unbonded length of the anchor are able to stretch under the imposed incremental seismic loads. In most cases, the amount of elastic elongation in the strand or bar under the incremental seismic load is sufficient to develop seismic active earth pressures but may not be sufficient to allow the horizontal seismic acceleration coefficient, $k_{h0}$, and associated earth pressure to be reduced to account for permanent horizontal wall displacement. The ability of the wall to deform laterally should be specifically investigated before reducing $k_{h0}$ to account for horizontal wall displacement.

The passive pressure for the embedded portion of the soldier pile or sheet pile wall also plays a part in the stability assessment, as it helps provide stability for the portion of the wall below the lowest anchor. This passive pressure is subject to seismically induced inertial forces that will reduce the passive resistance relative to the static capacity of the pile or wall section. Most often, the embedded portion of the pile involves discrete structural members spaced at 8.0 to 10.0 ft; however, the embedded portion could also involve a continuous wall in the case of a sheet pile or secant pile wall.

Anchors should be located behind the failure surface associated with the calculation of $P_{AE}$. The location of this failure surface can be determined using either the wedge equilibrium or the generalized limit equilibrium (slope stability) method. Note that this failure surface will likely be flatter than the requirements for anchor location under static loading. When using the wedge equilibrium or the generalized limit equilibrium method, $P_{AE}$ and its associated critical surface should be determined without the anchor forces.

Once the location of the anchor bond zone is defined, an external stability check should be conducted with the anchor forces included, using the anchor test load to define ultimate anchor capacities. This check is performed to confirm that the $C/D$ ratio is greater than 1.0. Under this loading condition, the critical surface will flatten and could pass through or behind some anchors. However, as long as the $C/D$ ratio is greater than 1.0, the design is satisfactory.

If the $C/D$ ratio is less than 1.0, either the unbonded length of the anchor must be increased or the length of the grouted zone must be lengthened. The design check would then be repeated.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The global stability check is performed to confirm that a slope stability failure does not occur below the anchored wall; external stability is checked to confirm the anchors will have sufficient reserve capacity to meet seismic load demands; and internal stability is checked to confirm that moments and shear forces within the structural members, including the anchor strand or bar tensile loads and the head connection, are within acceptable levels for the seismic load.

### 11.9.7—Corrosion Protection

Prestressed anchors and anchor heads shall be protected against corrosion consistent with the ground and groundwater conditions at the site. The level and extent of corrosion protection shall be a function of the ground environment and the potential consequences of an anchor failure. Corrosion protection shall be applied in accordance with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Section 6, "Ground Anchors."

### C11.9.7

Corrosion protection for piles, wales, and miscellaneous hardware and material should be consistent with the level of protection for the anchors and the design life of the structure.

### 11.9.8—Construction and Installation

#### 11.9.8.1—Anchor Stressing and Testing

All production anchors shall be subjected to load testing and stressing in accordance with the provisions of the *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5, "Testing and Stressing." Preproduction load tests may be specified when unusual conditions are encountered to verify the safety with respect to the design load to establish the ultimate anchor load (pullout test), or to identify the load at which excessive creep occurs.

At the end of the testing of each production anchor, the anchor should be locked off to take up slack in the anchored wall system to reduce post-construction wall deformation. The lock-off load should be determined and applied as described in the *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5.6.

#### C11.9.8.1

Common anchor load tests include pullout tests performed on sacrificial preproduction anchors and creep, performance, and proof tests performed the production anchors. None of the production anchor tests determine the actual ultimate anchor load capacity. The production anchor test results only provide an indication of serviceability under a specified load. Performance tests consist of incremental loading and unloading of anchors to verify sufficient capacity to resist the test load, verify the free length, and evaluate the permanent set of the anchor. Proof tests, usually performed on each production anchor, consist of a single loading and unloading cycle to verify sufficient capacity to resist the test load and to prestress the anchor. Creep tests, recommended for cohesive soils with a plasticity index greater than 20 percent or a liquid limit greater than 50 percent, and highly weathered, soft rocks, consist of incremental, maintained loading of anchors to assess the potential for loss of anchor bond capacity due to ground creep.

Pullout tests should be considered in the following circumstances:

- If the preliminary anchor design using unit bond stresses provided in the previous tables indicate that anchored walls are marginally infeasible, requiring that a more accurate estimate of anchor capacity be obtained during wall design. This may occur due to lack of adequate room laterally to accommodate the estimated anchor length within the available right-of-way or easement.
- If the anticipated anchor installation method or soil/rock conditions are significantly different than those assumed to develop the presumptive

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

values in Tables C11.9.4.2-1 through C11.4.9.2-3 and inadequate site-specific experience is available to make a reasonably accurate estimate of the soil/rock–grout anchor bond stresses.

The FHWA recommends load testing anchors to 125 percent to 150 percent of the unfactored design load, Cheney (1984). Maximum load levels between 125 percent and 200 percent have been used to evaluate the potential for tendon overstress in service, to accommodate unusual or variable ground conditions or to assess the effect of ground creep on anchor capacity. Test load levels greater than 150 percent of the unfactored design load are normally applied only to anchors in soft cohesive soil or unstable soil masses where loss of anchor prestress due to creep warrants evaluation. The area of prestressing steel in the test anchor tendon may require being increased to perform these tests.

Note that the test details provided in the *AASHTO LRFD Bridge Construction Specifications*, Article 6.5.5, at least with regard to the magnitude of the incremental test loads, were developed for allowable stress design. These incremental test loads should be divided by the load factor for apparent earth pressure for anchored walls provided in Table 3.4.1-2 when testing to factored anchor loads.

Typically, the anchor lock-off load is equal to 80 to 100 percent of the nominal (unfactored) anchor load to ensure that the slack in the anchored wall system is adequately taken up so that post-construction wall deformation is minimized. However, a minimum lock-off load of 50 percent is necessary to properly engage strand anchor head wedges.

### 11.9.9—Drainage

The provisions of Article 11.8.8 shall apply.

### C11.9.9

Thin drains at the back of the wall face may not completely relieve hydrostatic pressure and may increase seepage forces on the back of the wall face due to rainwater infiltration, Terzaghi and Peck (1967), and Cedergren (1989). The effectiveness of drainage control measures should be evaluated by seepage analyses.

## 11.10—MECHANICALLY STABILIZED EARTH WALLS

### 11.10.1—General

MSE walls may be considered where conventional gravity, cantilever, or counterforted concrete retaining walls and prefabricated modular retaining walls are considered, and particularly where substantial total and differential settlements are anticipated.

When two intersecting walls form an enclosed angle of 70 degrees or less, the affected portion of the wall shall be designed as an internally tied bin structure with at-rest earth pressure coefficients.

### C11.10.1

Mechanically stabilized earth (MSE) systems, whose elements may be proprietary, employ either metallic (strip or grid type) or geosynthetic (geotextile, strip, or geogrid) tensile reinforcements in the soil mass, and a facing element which is vertical or near vertical. MSE walls behave as a gravity wall, deriving their lateral resistance through the dead weight of the reinforced soil mass behind the facing. For relatively thick facings, the dead weight of the facing may also provide a significant

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

MSE walls shall not be used under the following conditions:

- Where utilities other than highway drainage are to be constructed within the reinforced zone unless access is provided to utilities without disrupting reinforcements and breakage or rupture of utility lines will not have a detrimental effect on the stability of the structure.
- Where floodplain erosion or scour may undermine the reinforced fill zone or facing, or any supporting footing.
- With reinforcements exposed to surface or ground water contaminated by acid mine drainage, other industrial pollutants, or other environmental conditions defined as aggressive in Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, unless environmental-specific, long-term corrosion, or degradation studies are conducted.

contribution to the capacity of the wall system. Typical MSE walls are shown in Figure C11.10.1-1.

All available data indicate that corrosion in MSE walls is not accelerated by stray currents from electric rail lines due to the discontinuity of the earth reinforcements in a direction parallel to the source of the stray current. Where metallic reinforcements are used in areas of anticipated stray currents within 200 ft of the structure, and the metallic reinforcements are continuously connected in a direction parallel to the source of stray currents, a corrosion expert should evaluate the potential need for corrosion control requirements. More detailed information on stray current corrosion issues is provided by Sankey and Anderson (1999).

Where future access to utilities may be gained without disrupting reinforcements and where leakage from utilities would not create detrimental hydraulic conditions or degrade reinforcements, utilities in the reinforced zone may be acceptable.

The potential for catastrophic failure due to scour is high for MSE walls if the reinforced fill is lost during a scour occurrence. Consideration may be given to lowering the base of the wall or to alternative methods of scour protection, such as sheetpile walls and/or riprap of sufficient size, placed to a sufficient depth to preclude scour.

All rights reserved. Duplication is a violation of applicable law.

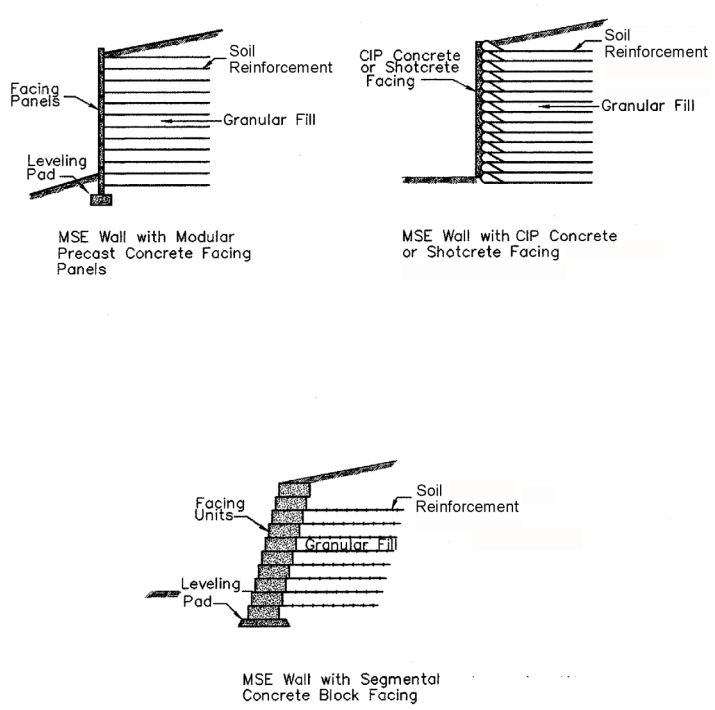

**Figure C11.10.1-1—Typical Mechanically Stabilized Earth Walls**

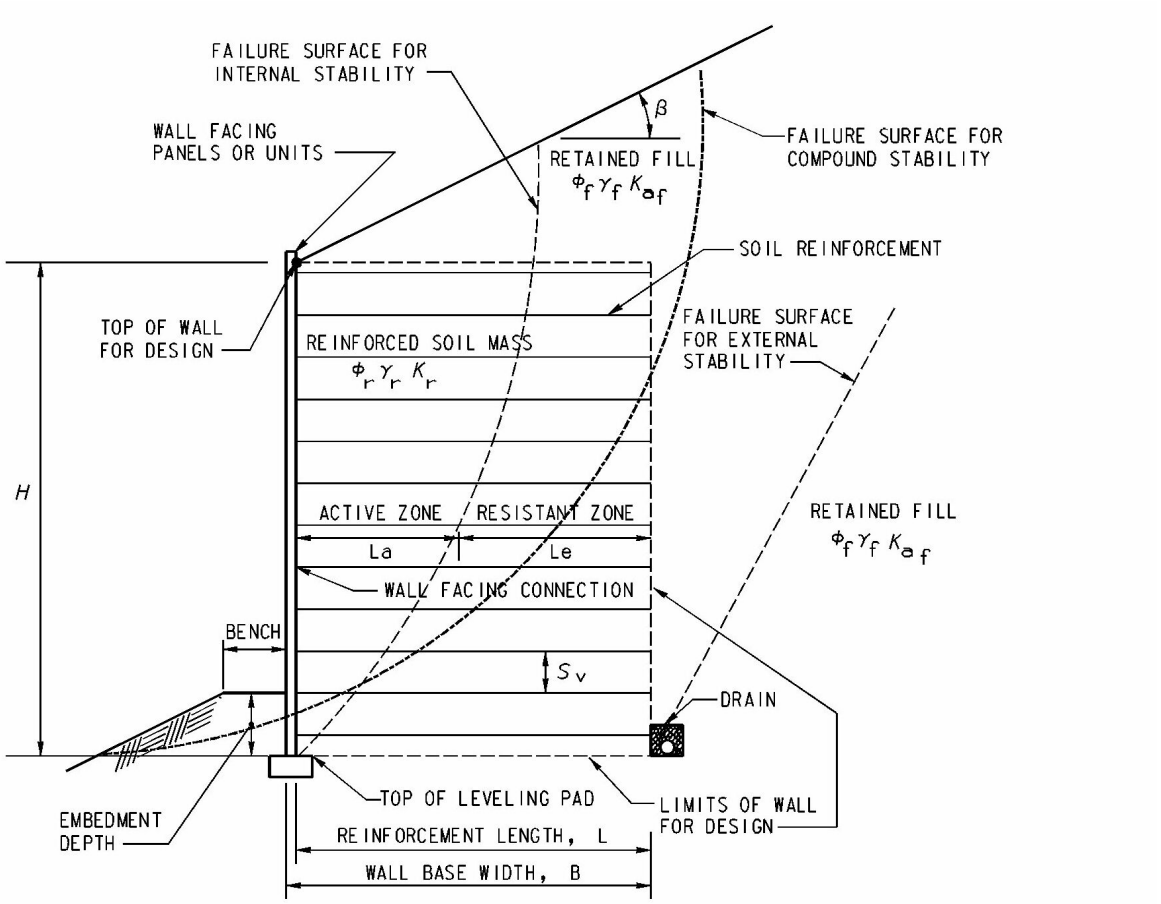
MSE walls shall be designed for external stability of the wall system as well as internal stability of the reinforced soil mass behind the facing. Overall and compound stability failure shall be considered. Structural design of the wall facing shall also be considered.

The specifications provided herein for MSE walls do not apply to geometrically complex MSE wall systems such as tiered walls (walls stacked on top of one another), back-to-back walls, or walls which have trapezoidal sections. Design guidelines for these cases are provided in FHWA-NHI-10-024 (Berg et al., 2009). Compound stability should also be evaluated for these complex MSE wall systems (see Article 11.10.5.6).

For simple structures with rectangular geometry, relatively uniform reinforcement spacing, and a near vertical face, compound failures passing both through the unreinforced and reinforced zones will not generally be critical. However, if complex conditions exist such as changes in reinforced soil types or reinforcement lengths, high surcharge loads, sloping faced structures, a slope at the toe of the wall, or stacked structures, compound failures must be considered.

Internal design of MSE wall systems requires knowledge of short- and long-term properties of the materials used as soil reinforcements as well as the soil mechanics which govern MSE wall behavior.



### 11.10.2—Structure Dimensions

An illustration of the MSE wall element dimensions required for design is provided in Figure 11.10.2-1.

The size and embedment depth of the reinforced soil mass shall be determined based on:

- Requirements for stability and geotechnical strength, as specified in Article 11.10.5 consistent with requirements for gravity walls,
- Requirements for structural resistance within the reinforced soil mass itself, as specified in Article 11.10.6, for the panel units, and for the development of reinforcement beyond assumed failure zones, and
- Traditional requirements for reinforcement length not less than 70 percent of the wall height, except as noted in Article 11.10.2.1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For external and internal stability calculations, the weight and dimensions of the facing elements are typically ignored. However, it is acceptable to include the facing dimensions and weight in sliding and bearing capacity calculations. For internal stability calculations, the wall dimensions are considered to begin at the back of the facing elements.

**Figure 11.10.2-1—MSE Wall Element Dimensions Needed for Design**

### 11.10.2.1—Minimum Length of Soil Reinforcement

For sheet-, strip-, and grid-type reinforcement, the minimum soil reinforcement length shall be 70 percent of the wall height as measured from the leveling pad. Reinforcement length shall be increased as required for surcharges and other external loads, or for soft foundation soils.

The reinforcement length shall be uniform throughout the entire height of the wall, unless

### C11.10.2.1

In general, a minimum reinforcement length of 8.0 ft, regardless of wall height, has been recommended based on historical practice, primarily due to size limitations of conventional spreading and compaction equipment. Shorter minimum reinforcement lengths, on the order of 6.0 ft, but no less than 70 percent of the wall height, can be considered if smaller compaction equipment is used, facing panel alignment can be maintained, and minimum requirements for wall external stability are met.

Significant shortening of the reinforcement elements below the minimum recommended ratio of 0.7*H* may only be considered when accurate, site specific determinations of the strength of the unreinforced fill and the foundation soil have been made. Christopher et al. (1990) presents results which strongly suggest that shorter reinforcing length to height ratios, i.e., 0.5*H* to 0.6*H*, substantially increase horizontal deformations.

A nonuniform reinforcement length may be considered under the following circumstances:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

substantiating evidence is presented to indicate that variation in length is satisfactory.

- Lengthening of the uppermost reinforcement layers to beyond 0.7$H$ to meet pullout requirements, or to address seismic or impact loads.
- Lengthening of the lowermost reinforcement layers beyond 0.7$H$ to meet overall (global) stability requirements based on the results of a detailed global stability analysis.
- Shortening of the bottom reinforcement layers to less than 0.7$H$ to minimize excavation requirements, provided the wall is bearing on rock or very competent foundation soil (see below).

For walls on rock or very competent foundation soil, e.g., $SPT$ > 50, the bottom reinforcements may be shortened to a minimum of 0.4$H$ with the upper reinforcements lengthened to compensate for external stability issues in lieu of removing rock or competent soil for construction. Design guidelines for this case are provided in FHWA-NHI-10-024 (Berg et al., 2009).

For conditions of marginal stability, consideration must be given to ground improvement techniques to improve foundation stability, or to lengthening of reinforcement.

### 11.10.2.2—Minimum Front Face Embedment

The minimum embedment depth of the bottom of the reinforced soil mass (top of the leveling pad) shall be based on bearing resistance, settlement, and stability requirements determined in accordance with Section 10.

Unless constructed on rock foundations, the embedment at the front face of the wall in ft shall not be less than:

- a depth based on the prevailing depth of frost penetration, if the soil below the wall is frost-susceptible, and the external stability requirement, and
- 2.0 ft on sloping ground (4.0$H$:1$V$ or steeper) or where there is potential for removal of the soil in front of the wall toe due to erosion or future excavation, or 1.0 ft on level ground where there is no potential for erosion or future excavation of the soil in front of the wall toe.

For walls constructed along rivers and streams, embedment depths shall be established at a minimum of 2.0 ft below potential scour depth as determined in accordance with Article 11.6.3.5.

As an alternative to locating the wall base below the depth of frost penetration where frost-susceptible soils are present, the soil within the depth and lateral extent of frost penetration below the wall can be removed and replaced with nonfrost-susceptible clean granular soil.

A minimum horizontal bench width of 4.0 ft shall be provided in front of walls founded on slopes. The bench

### C11.10.2.2

The minimum embedment guidelines provided in Table C11.10.2.2-1 may be used to preclude local bearing resistance failure under the leveling pad or footing due to higher vertical stresses transmitted by the facing.

**Table C11.10.2.2-1—Guide for Minimum Front Face Embedment Depth**

| Slope in Front of Structures | | Minimum Embedment Depth |
|---|---|---|
| Horizontal | for walls | $H$/20.0 |
| | for abutments | $H$/10.0 |
| 3.0$H$:1.0$V$ | walls | $H$/10.0 |
| 2.0$H$:1.0$V$ | walls | $H$/7.0 |
| 1.5$H$:1.0$V$ | walls | $H$/5.0 |

For structures constructed on slopes, minimum horizontal benches are intended to provide resistance to local bearing resistance failure consistent with resistance to general bearing resistance failure and to provide access for maintenance inspections.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

may be formed or the slope continued above that level as shown in Figure 11.10.2-1.

The lowest backfill reinforcement layer shall not be located above the long-term ground surface in front of the wall.

**11.10.2.3—Facing**

Facing elements shall be designed to resist the horizontal force in the soil reinforcements at the reinforcement to facing connection, as specified in Articles 11.10.6.2.2 and 11.10.7.3.

In addition to these horizontal forces, the facing elements shall also be designed to resist potential compaction stresses occurring near the wall face during erection of the wall.

The tension in the reinforcement may be assumed to be resisted by a uniformly distributed earth pressure on the back of the facing.

The facing shall be stabilized such that it does not deflect laterally or bulge beyond the established tolerances.

*11.10.2.3.1—Stiff or Rigid Concrete, Steel, and Timber Facings*

Facing elements shall be structurally designed in accordance with Sections 5, 6, and 8 for concrete, steel, and timber facings, respectively.

The minimum thickness for concrete panels at, and in the zone of stress influence of, embedded connections shall be 5.5 in. and 3.5 in. elsewhere. The minimum concrete cover shall be 1.5 in. Reinforcement shall be provided to resist the average loading conditions for each panel. Temperature and shrinkage steel shall be provided as specified in Article 5.10.6.

The structural integrity of concrete face panels shall be evaluated with respect to the shear and bending moment between reinforcements attached to the facing panel in accordance with Section 5.

For segmental concrete facing blocks, facing stability calculations shall include an evaluation of the maximum vertical spacing between reinforcement layers, the maximum allowable facing height above the uppermost reinforcement layer, inter-unit shear capacity, and resistance of the facing to bulging. The maximum spacing between reinforcement layers shall be limited to twice the width, $W_u$ illustrated in Figure 11.10.6.4.4b-1, of the segmental concrete facing block unit or 2.7 ft, whichever is less, subject to the limitations provided in Article 11.10.6.2.1. The maximum facing height up to the wall surface grade above the uppermost reinforcement layer shall be limited to $1.5W_u$ illustrated in Figure 11.10.6.4.4b-1 or 24.0 in., whichever is less, provided that the facing above the uppermost reinforcement layer is demonstrated to be stable against a toppling failure through detailed calculations. The maximum depth of facing below the lowest reinforcement layer shall be limited to the width, $W_u$, of the proposed segmental concrete facing block unit.

**C11.10.2.3**

See Article C3.11.2 for guidance. Additional information on compaction stresses can be found in Duncan and Seed (1986) and Duncan et al. (1991). Alternatively, compaction stresses can be addressed through the use of facing systems which have a proven history of being able to resist the compaction activities anticipated behind the wall and which have performed well in the long-term.

*C11.10.2.3.1*

The specified minimum panel thicknesses and concrete cover recognize that MSE walls are often employed where panels may be exposed to salt spray and/or other corrosive environments. The minimum thicknesses also reflect the tolerances on panel thickness, and placement of reinforcement and connectors that can reasonably be conformed to in precast construction.

Based on research by Allen and Bathurst (2015), facings consisting of segmental concrete facing blocks behave as a stiff facing, due to the ability of the facing blocks to transmit moment in a vertical direction throughout the facing column, and appear to have even greater stiffness than incremental precast concrete panels.

Experience has shown that for walls with segmental concrete block facings, the gap between soil reinforcement sections or strips at a horizontal level should be limited to a maximum of one block width to limit bulging of the facing between reinforcement levels or build-up of stresses that could result in performance problems. The ability of the facing to carry moment horizontally to bridge across the gaps in the reinforcement horizontally should be evaluated if horizontally discontinuous reinforcement is used, i.e., a reinforcement coverage ratio $R_c < 1$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*11.10.2.3.2—Flexible Wall Facings*

If welded wire, expanded metal, or similar facing is used, it shall be designed in a manner which prevents the occurrence of excessive bulging as backfill behind the facing compresses due to compaction stresses or self-weight of the backfill. This may be accomplished by limiting the size of individual facing elements vertically and the vertical and horizontal spacing of the soil reinforcement layers, and by requiring the facing to have an adequate amount of vertical slip and overlap between adjacent elements.

The top of the flexible facing at the top of the wall shall be attached to a soil reinforcement layer to provide stability to the top facing.

Geosynthetic facing elements shall not, in general, be left exposed to sunlight (specifically ultraviolet radiation) for permanent walls. If geosynthetic facing elements must be left exposed permanently to sunlight, the geosynthetic shall be stabilized to be resistant to ultraviolet radiation. Product-specific test data shall be provided which can be extrapolated to the intended design life and which proves that the product will be capable of performing as intended in an exposed environment.

*C11.10.2.3.2*

Experience has shown that for welded wire, expanded metal, or similar facings, vertical reinforcement spacing should be limited to a maximum of 2.0 ft and the gap between soil reinforcement at a horizontal level limited to a maximum of 3.0 ft to limit bulging of the panels between reinforcement levels. The section modulus of the facing material should be evaluated and calculations provided to support reinforcement spacings, which will meet the bulging requirements stated in Article C11.10.4.2.

*11.10.2.3.3—Corrosion Issues for MSE Facing*

Steel-to-steel contact between the soil reinforcement connections and the concrete facing steel reinforcement shall be prevented so that contact between dissimilar metals, e.g., bare facing reinforcement steel and galvanized soil reinforcement steel, does not occur.

A corrosion protection system shall be provided where salt spray is anticipated.

*C11.10.2.3.3*

Steel-to-steel contact in this case can be prevented through the placement of a nonconductive material between the soil reinforcement face connection and the facing concrete reinforcing steel. Examples of measures which can be used to mitigate corrosion include, but are not limited to, coatings, sealants, or increased panel thickness.

**11.10.3—Loading**

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered to come in contact with steel wall elements.

**11.10.4—Movement at the Service Limit State**

**11.10.4.1—Settlement**

The provisions of Article 11.6.2 shall apply as applicable.

The allowable settlement of MSE walls shall be established based on the longitudinal deformability of the facing and the ultimate purpose of the structure.

**C11.10.4.1**

For systems with rigid concrete facing panels and with a maximum joint width of 0.75 in., the maximum tolerable slope resulting from calculated differential settlement may be taken as given in Table C11.10.4.1-1.

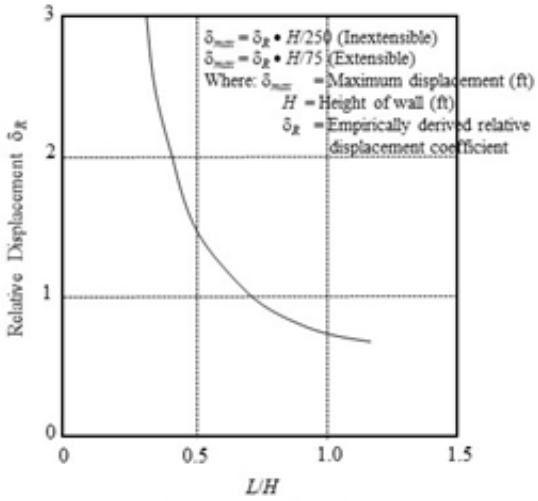
© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Where foundation conditions indicate large differential settlements over short horizontal distances, vertical full-height slip joints shall be provided.

Differential settlement from the front to the back of the wall shall also be evaluated, especially regarding the effect on facing deformation, alignment, and connection stresses.

**Table C11.10.4.1-1—Guide for Limiting Distortion for Precast Concrete Facings of MSE Walls**

| Joint Width (in.) | Limiting Differential Settlement | |
|---|---|---|
| | Area ≤ 30 ft$^2$ | 30 ft$^2$ ≤ Area ≤ 75 ft$^2$ |
| 0.75 | 1/100 | 1/200 |
| 0.50 | 1/200 | 1/300 |
| 0.25 | 1/300 | 1/600 |



For MSE walls with full height precast concrete facing panels, total settlement should be limited to 2.0 in., and the limiting differential settlement should be 1/500. For walls with segmental concrete block facings, the limiting differential settlement should be 1/200. For walls with welded wire facings or walls in which cast-in-place concrete or shotcrete facing is placed after wall settlement is essentially complete, the limiting differential settlement should be 1/50. These limiting differential settlement criteria consider only structural needs of the facing. More stringent differential settlement criteria may be needed to meet aesthetic requirements.

### 11.10.4.2—Lateral Displacement

Lateral wall displacements shall be estimated as a function of overall structure stiffness, compaction intensity, soil type, reinforcement length, slack in reinforcement-to-facing connections, and deformability of the facing system or based on monitored wall performance.

### C11.10.4.2

A first order estimate of lateral wall displacements occurring during wall construction for simple MSE walls on firm foundations can be obtained from Figure C11.10.4.2-1. If significant vertical settlement is anticipated or heavy surcharges are present, lateral displacements could be considerably greater. Figure C11.10.4.2-1 is appropriate as a guide to establish an appropriate wall face batter to obtain a near vertical wall or to determine minimum clearances between the wall face and adjacent objects or structures.

Based on 20 ft high walls, relative displacement increases approximately 25 percent for every 400 psf of surcharge. Experience indicates that for higher walls, the surcharge effect may be greater.

Note: This figure is only a guide. Actual displacement will depend, in addition to the parameters address in the figure, on soil characteristics, compaction effort, and contractor workmanship.

**Figure C11.10.4.2-1—Empirical Curve for Estimating Anticipated Lateral Displacement during Construction for MSE Walls**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For additional explanation on how to use this figure, see Berg et al. (2009).

For welded wire or similarly faced walls such as gabion faced walls, the maximum tolerable facing bulge between connections, both horizontally and vertically, with soil reinforcement is approximately 2.0 in. For geosynthetic facings, the maximum facing bulge between reinforcement layers should be approximately 2.75 in. for 1.0 ft vertical reinforcement spacing to 5.0 in. for 2.0 ft vertical reinforcement spacing.

In cases where significant deformation of the wall face during or after wall construction is unavoidable, adjustment to the wall face batter should be considered. Additional facing offset at the wall toe may be needed to prevent buildup of lateral stress on existing structures in front of the wall, including more rigid second stage facing placed during or after wall construction.

### 11.10.4.3—Soil Failure (Internal Stability)

For reinforcement load prediction methods developed empirically from measurements, the wall shall be designed to prevent failure of the soil within the reinforced soil mass, thus preserving the conditions under which the empirical data were obtained. Reinforced fill soil failure is defined to occur when the strain in the reinforcement exceeds a value sufficient to allow the soil to reach or exceed its peak shear strength, and a contiguous shear failure zone within the reinforced wall backfill develops.

For the Stiffness Method as described in Article 11.10.6.2.1e, to prevent soil failure, the reinforcement strain $\varepsilon_{rein}$ in individual layers shall be as follows for extensible reinforcement:

$$\varepsilon_{rein} = \frac{\gamma_{p-EVsf} T_{\max}}{\phi_{sf} J_i} \le \varepsilon_{mxmx} \qquad (11.10.4.3\text{-}1)$$

where:

$\varepsilon_{rein}$ = the reinforcement strain in any individual reinforcement layer corresponding to $T_{max}$ (%)

$\gamma_{p\text{-}EVsf}$ = load factor for prediction of $T_{max}$ for the soil failure limit state (dim.)

$T_{max}$ = the maximum load in the reinforcement at each reinforcement level, as specified in Article 11.10.6.2.1e (kips/ft)

$\phi_{sf}$ = resistance factor that accounts for uncertainty in the measurement of the reinforcement stiffness at the specified strain (dim.)

$J_i$ = reinforcement layer secant stiffness (kips/ft)

$\varepsilon_{mxmx}$ = maximum acceptable strain in the wall cross-section corresponding to $T_{max}$ in any reinforcement layer (%)

### C11.10.4.3

Soil failure for internal stability of MSE walls is considered a service limit state for design because it is based on a deformation criterion. Furthermore, if this criterion is substantially exceeded, the structure will not collapse but will more likely develop progressive increases in facing deformation.

Research indicates that if the average peak reinforcement strain in the wall exceeds 2.5 to 3 percent, for typical granular backfill materials, soil failure can occur (Allen et al., 2003) (Allen and Bathurst, 2013; 2015; 2018). Since $\varepsilon_{mxmx}$ is a deterministic limit, $\varepsilon_{mxmx}$ is set 0.5 percent lower than this to provide an additional margin of safety to ensure that soil failure does not occur.

Of the three empirically-based design methods used to estimate reinforcement loads, only the Stiffness Method directly addresses soil failure. Historically, the other two empirically based methods identified in these Specifications (i.e., the Simplified and Coherent Gravity methods) have been safely used without directly assessing soil failure as a limit state. For geosynthetic walls, these two methods have been demonstrated to be overly conservative relative to measured values (Allen et al., 2003) (Allen and Bathurst 2002; 2013; 2014a, 2014b) (Bathurst et al., 2008) (Rowe and Ho 1993), and for steel reinforced walls, the requirement to be below $F_y$ ensures that the strains in the system remain very low. Therefore, soil failure is not required to be assessed for the Simplified and Coherent Gravity methods.

Regarding the Limit Equilibrium Method, failure of both the reinforcement and the soil are addressed in the strength limit state (Leshchinsky et al., 2016).

For design using the Stiffness Method, this limit state tends to control the strength of the reinforcement needed, especially in the upper half of the wall. The stiffness used to meet this limit state should be determined as a first step. Subsequently, this minimum required stiffness is used to determine $T_{max}$ for the reinforcement rupture, connection rupture, and pullout limit states. The ultimate reinforcement tensile strength, $T_{ult}$, required to meet the

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$J_i$, the reinforcement layer secant stiffness, should be determined at a strain of 2 percent for geogrids and geotextiles. $J_i$ should be determined at 1,000 hrs or the estimated time to complete the wall, as specified in AASHTO R 69. $\phi_{sf}$ is as specified in Table 11.5.7-1.

The maximum acceptable strain in each reinforcement layer $\varepsilon_{mxmx}$ corresponding to $T_{max}$ should be set at 2 percent strain for stiff faced walls and 2.5 percent strain for flexible faced walls. These criteria have the objective of preventing the development of a contiguous shear surface though the reinforced soil zone.

For steel reinforced walls, soil failure does not need to be evaluated, provided the final design steel stress is less than $F_y$.

reinforcement rupture and connection rupture limits may be less than the ultimate tensile strength of geosynthetic products with the minimum stiffness needed to prevent soil failure. In this case, prevention of soil failure is controlling the strength of the geosynthetic reinforcement needed. Geosynthetic reinforcement test report data which provide the relationship between reinforcement stiffness and $T_{ult}$ are available from AASHTO NTPEP.

For additional details and examples of how to assess the prevention of soil failure when using the Stiffness Method, see Allen and Bathurst (2018).

For geostrip walls, working strains tend to be lower than for other geosynthetics based on strain measurements observed in full-scale geostrip walls (Miyata et al., 2018), and $J_i$ determined at a strain level of 1 percent may be more appropriate.

### 11.10.5—Safety against Soil Failure (External Stability)

#### 11.10.5.1—General

MSE structures shall be proportioned to satisfy eccentricity and sliding criteria normally associated with gravity structures.

Safety against soil failure shall be evaluated by assuming the reinforced soil mass to be a rigid body. The coefficient of active earth pressure, $k_a$, used to compute the earth pressure of the retained soil behind the reinforced soil mass shall be determined using the friction angle of the retained soil. In the absence of specific data, a maximum friction angle of 30 degrees may be used for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

#### C11.10.5.1

Eccentricity requirements seldom govern design. Sliding and overall stability usually govern design of structures greater than 30.0 ft in height, structures constructed on weak foundation soils, or structures loaded with sloping surcharges.

#### 11.10.5.2—Loading

Lateral earth pressure distributions for external stability design of MSE walls shall be taken as specified in Article 3.11.5.8. Application of loads for external stability shall be taken as specified in Articles 11.10.5 and 11.10.6, respectively. Application of surcharge and other external loads shall be taken as specified in Articles 11.10.10 and 11.10.11. Application of load factors for these loads shall be taken as specified in Article 11.5.6.

#### C11.10.5.2

Figures 3.11.5.8.1-1, 3.11.5.8.1-2, and C3.11.5.8.1-1 illustrate lateral earth pressure distributions for external stability of MSE walls with horizontal backslope, inclined backslope, and broken backslope, respectively.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For external stability calculations only, the active earth pressure coefficients for retained backfill, i.e., fill behind the reinforced soil mass, shall be taken as specified in Article 3.11.5.3 with δ equal to no greater than 0.67 $\phi'_f$ of the reinforced zone or retained zone, whichever is less.

Dead load surcharges, if present, shall be taken into account in accordance with Article 11.10.10.

For investigation of sliding stability and eccentricity, the continuous traffic surcharge loads shall be considered to act beyond the end of the reinforced zone as shown in Figure 11.10.5.2-1. Application of load factors for these loads shall be taken as specified in Article 11.5.6.

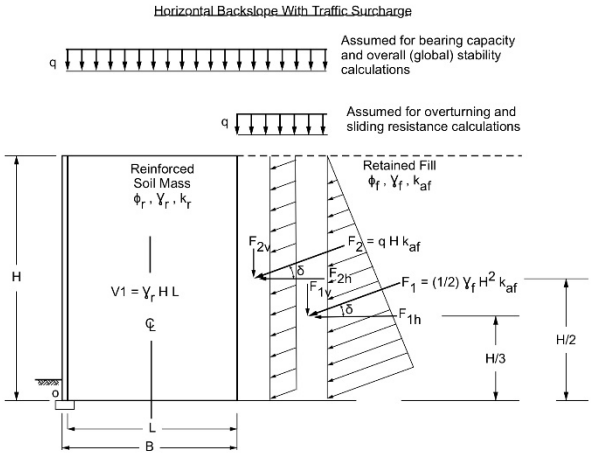


**Figure 11.10.5.2-1—External Stability for Wall with Horizontal Backslope and Traffic Surcharge**

### 11.10.5.3—Sliding

The provisions of Article 10.6.3.4 shall apply.

Sliding stability of MSE walls shall be evaluated at the base of the bottom of the wall facing and, as a minimum, at the interface between the soil and reinforcement for the lowest reinforcement layer. The coefficient of sliding friction at the base of the reinforced soil mass shall be determined using the friction angle of the foundation soil, $\phi_f$, or reinforced fill soil, $\phi_r$.

For discontinuous reinforcements, e.g., strips, the angle of sliding friction shall be taken as the lesser of $\phi_r$ of the reinforced fill and $\phi_f$ of the foundation soil. For continuous reinforcements, e.g., grids and sheets, the angle of sliding friction shall be taken as the lesser of $\phi_r$, $\phi_f$, and ρ, where ρ is the soil-reinforcement interface friction angle. In the absence of specific data, a maximum friction angle, $\phi_f$, of 30 degrees, $\phi_r$ of 34 degrees, and soil-reinforcement interface angle, ρ, of $^2/_3\phi_f$ or $^2/_3\phi_r$ should be used.

### C11.10.5.3

For relatively thick facing elements, it may be desirable to include the facing dimensions and weight in sliding and overturning calculations, i.e., use *B* in lieu of *L* as shown in Figure 11.10.5.2-1.

Testing of the foundation soil or the backfill soil should be considered so that less conservative friction angle values than the default minimums could be used to estimate sliding resistance. Test results that could be used for this purpose include laboratory soil shear strength or interface shear testing, or in-situ testing combined with correlations to soil shear strength.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

If the lowest reinforcement layer is above the bottom of the wall facing, to check sliding at the base of the wall, the friction angle of the foundation soil, $\phi_f$, or reinforced fill soil, $\phi_r$, whichever is less, shall be used to assess sliding resistance. To check sliding resistance at the lowest reinforcement layer in this case, since the reinforcement is fully within the reinforced fill, the interface friction angle, $\rho$, should be based on the friction angle for the reinforced fill, $\phi_r$.

**11.10.5.4—Bearing Resistance**

For the purpose of computing bearing resistance, an equivalent footing shall be assumed whose length is the length of the wall, and whose width is the length of the reinforcement strip at the foundation level. Bearing pressures shall be computed using a uniform base pressure distribution over an effective width of footing determined in accordance with the provisions of Articles 10.6.3.1 and 10.6.3.2.

Where soft soils or sloping ground in front of the wall are present, the difference in bearing stress calculated for the wall reinforced soil zone relative to the local bearing stress beneath the facing elements shall be considered when evaluating bearing capacity. In both cases, the leveling pad shall be embedded adequately to meet bearing capacity requirements.

**C11.10.5.4**

The effect of eccentricity and load inclination is accommodated by the introduction of an effective width, $B' = L-2e$, instead of the actual width.

For relatively thick facing elements, it may be reasonable to include the facing dimensions and weight in bearing calculations, i.e., use $B$ in lieu of $L$ as shown in Figure 11.10.2-1.

Note, when the value of eccentricity, $e$, is negative: $B' = L$.

Due to the flexibility of MSE walls, a triangular pressure distribution at the wall base cannot develop, even if the wall base is founded on rock, as the reinforced soil mass has limited ability to transmit moment. Therefore, an equivalent uniform base pressure distribution is appropriate for MSE walls founded on either soil or rock.

Concentrated bearing stresses from the facing weight on soft soil could create concentrated stresses at the connection between the facing elements and the wall backfill reinforcement.

**11.10.5.5—Overturning**

The provisions of Article 11.6.3.3 shall apply.

**C11.10.5.5**

Reinforced soil walls are in general too flexible to fail due to excessive eccentricity (i.e., overturning). However, meeting the eccentricity requirements for gravity walls specified in Article 11.6.3.3 will keep the reinforced soil wall from being too flexible in its response to lateral earth pressure and other lateral loads that may be present behind the reinforced soil wall. See Article C11.10.2.1 for additional explanation regarding the effect shorter reinforcement length may have on MSE wall flexibility and deformation.

**11.10.5.6—Overall and Compound Stability**

The provisions of Article 11.6.3.7 shall apply. Additionally, for MSE walls with complex geometrics, MSE walls on sloping ground (above or below the wall), walls located on soft or otherwise potentially unstable ground, and walls supporting foundation loads located above or just behind the soil reinforcement, compound failure surfaces which pass through a portion of the

**C11.10.5.6**

Development of LEA for MSE wall design is summarized in Leshchinsky et al. (2016 and 2017). LEA, using either a log spiral or circular failure surface, is described by Vahedifard et al. (2014 and 2016) and Leshchinsky et al. (2016 and 2017). Chapters 9 and 10 of FHWA-HIF-17-004 (Leshchinsky et al., 2016) also include detailed procedures and examples for use of LEA

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

reinforced soil mass as illustrated in Figure 11.10.5.6-1 shall be investigated. Limit equilibrium analyses shall be used to evaluate compound stability. The long-term strength of each backfill reinforcement layer intersected by the failure surface should be considered as resisting forces in the limit equilibrium slope stability analysis.

For the Limit Equilibrium Analysis (LEA), values of $T_{max}$ for each reinforcement layer crossed by the critical failure surface(s) shall be obtained.

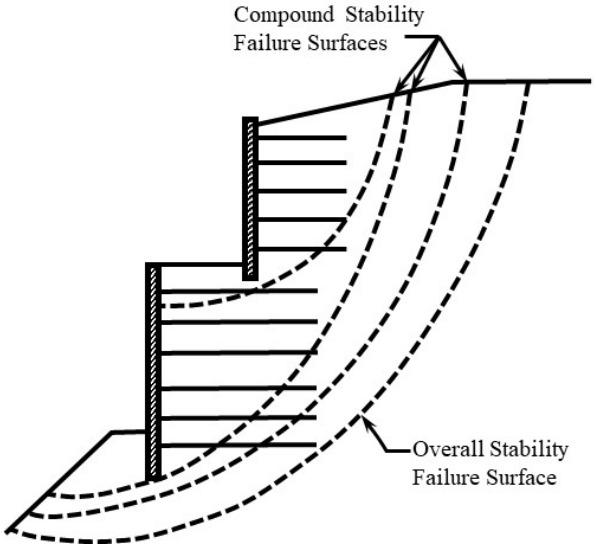

**Figure 11.10.5.6-1—Overall and Compound Stability of Complex MSE Wall Systems**

To perform a LEA for compound stability, three analysis steps shall be conducted, which are as follows:

1. Estimate the nominal load in each reinforcement layer, $T_{max}$, targeting a load and resistance factor combination of 1.0.
2. Adjust the reinforcement spacing and strength required to meet the limit states as specified in Articles 11.10.6.3 and 11.10.6.4 for each reinforcement layer using factored load and resistance values. Load factors shall be as specified in Tables 3.4.1-1 and 3.4.1-2, and resistance factors as specified in Table 11.5.7-1 and in Article 11.6.3.7.
3. Check the factored design using LEA with factored load and resistance values.

When additional surcharge loads, such as a structure footing load or live load, are applied to the top of the reinforced zone of the MSE wall, for Step 3, they shall be factored as specified in Article 3.4.1 for the Strength I limit state.

to evaluate and design geosynthetic walls. It is also possible to conduct the LEA using conventional slope stability computer software in which the tensile inclusions provide resistance to slope instability.

Note that in complex structures such as multi-tiered walls or high-strength retained soil (e.g., rock), the critical failure surface may reside entirely within the reinforced soil zone (e.g., see Leshchinsky et al., 2016).

LEA should not be used for internal stability design of MSE walls with inextensible (e.g., steel) reinforcement in lieu of empirically based procedures as specified in Article 11.10.6.2.1. Leshchinsky et al. (2016) indicate that inextensible reinforcements do not allow the soil strength to be fully mobilized, forcing the soil reinforcement to take on additional load. Allen and Bathurst (2018) provide a summary of measurements and LEA predictions which confirm these observations. With regard to extensibility of the reinforcement, see Allen and Bathurst (2018) and Leshchinsky et al. (2016) for guidance. However, for compound stability, use of LEA is the only available practical choice for both extensible and inextensible reinforced MSE walls.

For LEA, the resistance available in the wall is equal to the total long-term tensile strength, $T_{al}$, of the reinforcement layers available or the pullout resistance available at the intersection of each analyzed slip surface and each reinforcement layer, whichever controls the design. However, regarding $T_{al}$, working loads in geosynthetic reinforced MSE walls are usually low enough that strength loss due to creep is unlikely, since it is typically at the very end of the reinforcement design life that such strength loss occurs.

Geosynthetic MSE walls are generally not designed to stay in a state of limit equilibrium long-term after the wall face deformation becomes excessive, as it would normally be repaired or replaced at that point. Therefore, the reduction factors for creep and durability used for compound stability assessment can be reduced relative to the reduction factors needed for a 75- or 100-year degradation time period, since there should be plenty of warning as the wall approaches a state of limit equilibrium. For example, a durability reduction factor of near 1.0 and a creep reduction factor for the maximum limit equilibrium load of a few years may be sufficient for geosynthetic walls. However, for reinforcement strength loss mechanisms that occur near the beginning of the reinforcement design life or which result in continuous strength reduction throughout the design life, such as installation damage for geosynthetics, the full-strength reduction as specified in Article 11.10.6.4.3 should be applied to the available soil reinforcement tensile strength for compound stability.

For Step 1, a nominal value of $T_{max}$ from the limit equilibrium slope stability analyses is required to conduct the Strength and Extreme Event limit state analyses. To accomplish this, the LEA must be conducted to obtain reinforcement loads using a factor of safety of 1.0 (i.e., the combination of load and resistance factors is 1.0) to obtain unfactored values of $T_{max}$. Any external loads, such

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

as due to a foundation, are also left unfactored for this step. These nominal values of $T_{max}$ are then used to assess the spacing and strength of reinforcement required to meet all the Limit States in the next two steps.

For Step 2, the LRFD (factored) design is conducted as specified in Articles 11.10.6.3 and 11.10.6.4. If $T_{max}$ obtained in Step 1 does include the effect of the load caused by an external source such as a foundation, factoring $T_{max}$ using $\gamma_{p\text{-}EV}$ will approximate as much as practical the factored load for this step. This design is then checked in Step 3 using a limit equilibrium slope stability design model in which all loads and resistance values are factored. To accomplish this, the wall tensile reinforcement strength and pullout are factored as specified in Table 11.5.7-1, and the limit equilibrium slope stability analysis is conducted targeting a minimum factor of safety which is the reciprocal of the resistance factors specified in Article 11.6.3.7. If additional external loads such as due to a foundation are present, they are factored as specified in Article 3.4.1.

## 11.10.6—Safety against Structural Failure (Internal Stability)

### 11.10.6.1—General

Safety against structural failure shall be evaluated with respect to reinforcement rupture, reinforcement pullout behind the active zone, and connection rupture or pullout.

A preliminary estimate of the structural size of the stabilized soil mass may be determined on the basis of reinforcement pullout beyond the active zone, for which resistance is specified in Article 11.10.6.3.

### C11.10.6.1

The resistance factors, specified in Article 11.5.7, are consistent with the use of select backfill in the reinforced zone, homogeneously placed and carefully controlled in the field for conformance with Section 7 of the *AASHTO LRFD Bridge Construction Specifications,* and the use of drainage features necessary to keep the wall backfill well drained. The basis for the factors is the successful construction of thousands of structures in accordance with these criteria, and the use of conservative pullout resistance factors representing high confidence limits. Additionally, hundreds of reinforcement peak strain measurements from many well instrumented MSE walls combined with resistance statistics have been used to verify the resistance factors for internal stability for extensible (e.g., geosynthetic) MSE walls. For steel reinforced MSE walls, the calibration work is yet to be completed; therefore, the resistance factors for steel reinforced MSE walls are based on calibration by fitting to past practice.

### 11.10.6.2—Loading (Internal Stability)

The load in the reinforcement shall be determined at two critical locations: the zone of maximum stress and the connection with the wall face. Potential for reinforcement rupture and pullout are evaluated at the zone of maximum stress, which is assumed to be located at the boundary between the active zone and the resistant zone in Figure 11.10.2-1. Potential for reinforcement rupture and pullout are also evaluated at the connection of the reinforcement to the wall facing.

### C11.10.6.2

Loads carried by the soil reinforcement in mechanically stabilized earth walls are the result of vertical and lateral earth pressures, which exist within the reinforced soil mass, reinforcement extensibility, facing stiffness, wall toe restraint, and the stiffness and strength of the soil backfill within the reinforced soil mass. The soil reinforcement extensibility and material type are major factors in determining reinforcement load. In general, inextensible reinforcements consist of metallic strips, bar mats, or welded wire mats, whereas extensible

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The maximum friction angle used for the computation of horizontal force within the reinforced soil mass shall be assumed to be 34 degrees, unless the specific project select backfill is tested for frictional strength by triaxial or direct shear testing methods, AASHTO T 296 and T 297 or T 236, respectively. For internal stability, a design friction angle of greater than 40 degrees shall not be used with any reinforcement load prediction method, even if the measured friction angle is greater than 40 degrees.

reinforcements consist of geotextiles or geogrids, and geostrips. Inextensible reinforcements reach their peak strength at strains lower than the strain required for the soil to reach its peak strength. Extensible reinforcements reach their peak strength at strains greater than the strain required for soil to reach its peak strength. Additional guidelines regarding definition of extensibility are provided in Allen and Bathurst (2018).

Internal stability failure modes include soil reinforcement rupture, reinforcement pullout behind the active zone, and connection rupture or pullout. The service limit state is not evaluated for internal stability design with the exception of the soil failure limit state within the context of the Stiffness Method, as specified in Article 11.10.4.3.

Analysis of full-scale wall data in comparison to the widely accepted design methods such as the Coherent Gravity and Simplified methods (see Article 11.10.6.2.1) indicates that these methods will significantly underestimate reinforcement loads for inextensible steel reinforcement if design soil friction angles greater than 40 degrees are used. This recommendation applies to soil friction angles as determined using triaxial or direct shear tests, as the Simplified and Coherent Gravity methods were calibrated using triaxial or direct shear soil strengths (see Allen et al., 2001).

While it is possible to use a friction angle higher than 40 degrees for MSE walls with extensible reinforcement, long-term practice has been to not use higher friction angles for design for all MSE wall reinforcement types.

*11.10.6.2.1—Maximum Reinforcement Loads*

Maximum reinforcement loads, $T_{max}$, in each reinforcement layer shall be calculated using the following methods:

- the Coherent Gravity Method for inextensible (e.g., steel) reinforced MSE walls, and
- the Stiffness Method for extensible (e.g., geosynthetic) reinforced MSE walls.

The Simplified Method, provided in Appendix B11, is also acceptable to use for MSE wall design and applies to both steel and geosynthetic reinforced wall systems, but shall not be considered applicable to walls with a facing batter of greater than 20 degrees from vertical, unless $k_a$ is calculated for a wall face batter of no greater than 20 degrees.

The Coherent Gravity Method shall be applied to walls with inextensible (e.g., steel) soil reinforcement, and shall not be considered applicable to walls with a facing batter of greater than 20 degrees from vertical unless $k_a$ is calculated for a wall face batter of no greater than 20 degrees.

The Stiffness Method shall be applied to walls with extensible (e.g., geosynthetic) reinforcement, and shall not be considered applicable to walls with a facing batter of greater than 27 degrees from vertical.

*C11.10.6.2.1*

The methods outlined in these Specifications for predicting $T_{max}$ are empirically developed from measurements made during wall operational conditions. It is therefore important that these methods be applied to design situations that are within the range of the case history data used to develop them. For insights as to the range of the design situations applicable to the Coherent Gravity Method, see Schlosser (1978), Schlosser and Segrestin (1979), and Allen et al. (2001). Likewise, for the Simplified Method, included in Appendix B11, see Allen et al. (2001). Finally, for the Stiffness Method, see Allen and Bathurst (2015; 2018). If any of these methods must be used for situations that are significantly beyond their empirical basis, additional evaluations should be considered. Evaluations that should be considered to address internal stability and the determination of $T_{max}$ in such cases include the use of Limit Equilibrium Analysis (LEA) as described in Article 11.10.5.6, or possibly numerical modeling to assess the effect of the condition that is not within the empirical basis for the methods provided in Article 11.10.6.2.1 on $T_{max}$ for each reinforcement level. This is especially important for walls with complex geometry, walls with a facing batter of greater than 27 degrees, and walls in which compound stability should be evaluated as specified in Article 11.10.5.6.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The load factor for vertical earth pressure, $\gamma_{p\text{-}EV}$, shall be applied to $T_{max}$ when estimating the factored reinforcement layer load.

The Coherent Gravity Method has been used in MSE wall design practice for many years for steel reinforced wall systems. Detailed procedures for the Coherent Gravity Method are provided in Allen, et al. (2001) and in Mitchell and Villet (1987). This method requires the calculation of $k_a$. A wall face batter (or equivalent batter for a stepped wall) will reduce $k_a$ and the value of $T_{max}$ in the reinforcement layers. Based on measured data (Allen and Bathurst, 2015), $T_{max}$ in the reinforcement layers does not decrease as strongly with increasing facing batter as Coulomb analysis would indicate (see Article C11.10.6.2.1c for equations to estimate $k_a$). This is the reason for limiting the reduction in $k_a$ for this method.

For the Stiffness Method, the effect of wall face batter on $T_{max}$ can be assessed up to a facing batter of up to 27 degrees through the facing batter factor, $\Phi_{fb}$. However, the simplified form of the Stiffness Method equation (i.e., Eq. 11.10.6.2.1e-1) assumes this factor is equal to 1.0 for near vertical (i.e., a facing batter of 10 degrees or less) walls and will be conservative for a facing batter that is greater than 10 degrees.

The development of the Stiffness Method is provided in Allen and Bathurst (2015; 2018). This method considers the stiffness of the reinforcement and is empirically based. While it is generally applicable to all reinforcement and facing types, full scale, instrumented steel reinforced production walls designed with the Stiffness Method have yet to be built.

These MSE wall specifications also assume that inextensible reinforcements are not mixed with extensible reinforcements within the same wall. MSE walls which contain a mixture of inextensible and extensible reinforcements are not recommended.

The uncertainty in the load prediction method, and the applicable calibrated load factor, may be different for the different $T_{max}$ prediction methods. The original development of the load factor $\gamma_{p\text{-}EV}$, on the other hand, was conducted in consideration of vertical earth pressure exerted by a soil mass without inclusions, and was calibrated to address uncertainties implied by allowable stress design for external stability for walls. Research has been completed to quantify load prediction bias and uncertainty for the empirically based Stiffness Method, and is underway for the Coherent Gravity Method. For LEA, see Articles 11.10.5.6 and C11.10.5.6.

Other widely accepted and published design methods for calculation of reinforcement loads may be used at the discretion of the wall owner or approving agency, provided the designer develops method-specific load and resistance factors for the method employed.

*11.10.6.2.1a—Special Loading Conditions*

*C11.10.6.2.1a*

Soil surcharges above the reinforced soil wall zone shall be distributed as a uniform surcharge of thickness $S$ within a reinforced wall backfill width of $0.7H$ as shown in Figure 11.10.6.2.1a-1.

Sloping soil surcharges are taken into account through an equivalent uniform surcharge and assuming a level backslope condition. For these calculations, the depth, $Z$, is referenced from the top of

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Traffic live loads shall be positioned for extreme force effect. Traffic live load shall be distributed on the wall top as a uniform surcharge as shown in Figure 11.10.6.2.1a-2. The provisions of Article 3.11.6 shall apply.

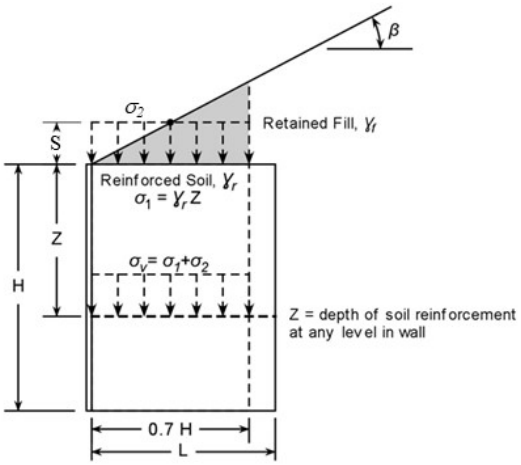

**Figure 11.10.6.2.1a-1—Calculation of Vertical Stress for Sloping Backslope Condition for Internal Stability Analysis**

$$\sigma_2 = S\gamma_f \qquad (11.10.6.2.1a\text{-}1)$$

where:

$S$ = average height of soil surcharge within 0.7H of back of wall face (ft)
$\gamma_f$ = unit weight of soil surcharge (lbs/ft$^3$)

For sloping surcharge:

$$S = (0.5)(0.7H)\tan\beta \qquad (11.10.6.2.1a\text{-}2)$$

For an irregular surcharge slope, $S$ = area of surcharge within 0.7$H$, divided by 0.7$H$.

Note: $H$ is the total height of the wall at the face. $Z$ is referenced from the top of the wall where the backfill intersects the back of wall facing.

the wall at the wall face, excluding any copings and appurtenances.

Note that $T_{max}$, the tensile load in the soil reinforcement, is calculated twice for internal stability design as follows: (1) for checking reinforcement and connection rupture, determine $T_{max}$ with live load surcharge included in the calculation of $\sigma_v$; (2) for checking pullout, determine $T_{max}$ with live load surcharge excluded from the calculation of $\sigma_v$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

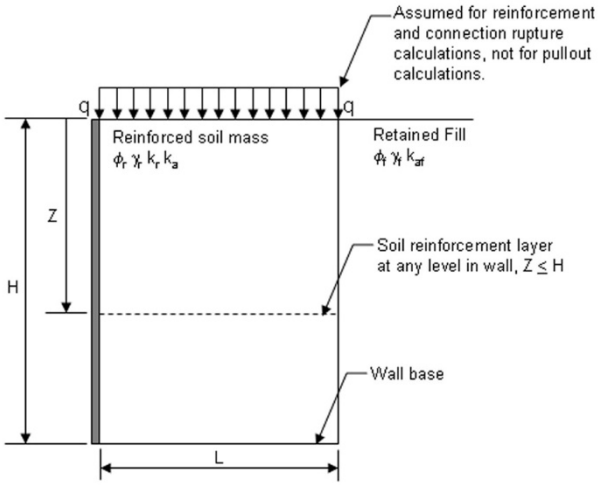

**Figure 11.10.6.2.1a-2—Calculation of Vertical Stress for Horizontal Backslope Condition, Including Live Load**

Additional vertical surcharge loads (e.g., due to structure foundations) as well as horizontal loads that must be resisted by the soil reinforcement shall be added to the lateral earth pressure due to reinforced soil backfill self-weight using superposition principles as specified in Article 11.10.10.

*11.10.6.2.1b—Reinforcement Spacing for Calculation of* $T_{max}$

*C11.10.6.2.1b*

For uniform vertical spacing of soil reinforcement, $S_v$, the tributary layer thickness, is equal to the vertical spacing of the reinforcement. For nonuniform vertical spacing of soil reinforcement, $S_v$, shall be taken as shown in Figure 11.10.6.2.1b-1.

A tributary layer thickness, $S_v$, greater than 2.7 ft should not be used without full-scale wall data (e.g., reinforcement loads and strains, and overall deflections) that support the acceptability of larger vertical spacing, except for MSE wall systems with facing units equal to or greater than 2.7 ft high with a minimum facing unit width, $W_u$, equal to or greater than the facing unit height. For these larger facing units the maximum spacing, $S_v$, shall not exceed the width of the facing unit, $W_u$, or 3.3 ft, whichever is less.

The design specifications provided herein assume that the wall facing combined with the reinforced backfill acts as a coherent unit to form a gravity retaining structure. Research by Allen et al. (2003) and Allen and Bathurst (2018) indicates that reinforcement loads increase linearly with increasing reinforcement spacing to a reinforcement vertical spacing of 2.7 ft or more, though a vertical spacing of this magnitude should not be attempted unless the facing is considered to be adequately stiff to prevent excessive bulging between layers (see Article C11.10.2.3.2).

In Figure 11.10.6.2.1b-1, not all reinforcement layers are shown, and this figure is only for illustrating concepts. Note that $S_v$ at the top of the wall for the first reinforcement layer is based on the level backfill case whether or not a sloping surcharge is present.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

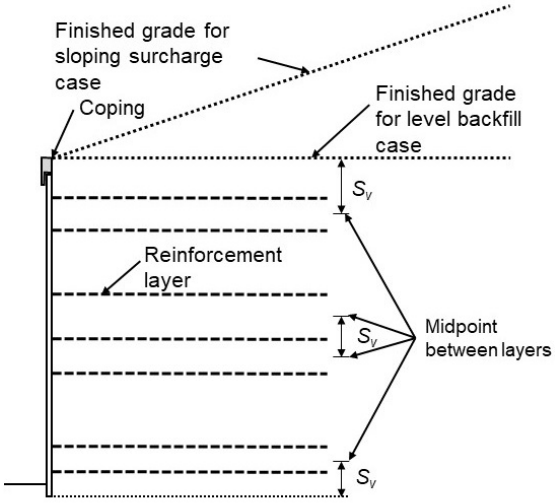

**Figure 11.10.6.2.1b-1—Determination of the Tributary Layer Thickness, $S_v$**

Horizontal spacing of reinforcement elements should not exceed 3.3 ft for walls with rigid facing panels. For walls with flexible facing panels, smaller horizontal gaps between soil reinforcement elements should be considered. Horizontal gaps between reinforcement elements shall be limited such that yielding of the steel, both in the facing and the soil reinforcement, and excessive deformation in the facing panels is prevented.

Regarding horizontal spacing of reinforcement elements, spacing as large as 3.3 ft has been used in typical design and construction practice for MSE walls. Back-analysis of instrumented MSE walls indicates that reinforcement load prediction accuracy is not adversely compromised with horizontal spacing of this magnitude when the reinforcement elements are directly attached to rigid facings such as precast concrete panels. However, for flexible facings such as welded wire, large horizontal spacing of the reinforcement has be shown to cause poor wall performance, such as excessive deformation and local yielding of the steel in either the facing element or the soil reinforcement, or both. Therefore, if horizontal gaps of this magnitude are used, the effect of the gaps on the facing panel deformation and stress in the steel should be investigated. See Article C11.10.4.2 for the definition of excessive deformation. With regard to steel stress, the stress level should be below yield both in the short term and long term.

*11.10.6.2.1c—Calculation of Lateral Earth Pressure Coefficients for Determination of $T_{max}$*

*C11.10.6.2.1c*

$k_a$ shall be determined using Eq. 3.11.5.3-1, assuming no wall friction and level backfill slope (i.e., $\delta = \beta$ and $\beta = 0$) for the empirically developed methods (e.g., the Coherent Gravity and Stiffness methods).

$k_o$ shall be determined using Eq. 3.11.5.2-1.

The assumption of no wall friction and level backfill slope (i.e., $\delta = \beta$ and $\beta = 0$) is consistent with the empirical development of the Simplified, Coherent Gravity, and Stiffness methods for estimating $T_{max}$ in each reinforcement layer. Since the Limit Equilibrium Method is theoretical (i.e., not empirically calibrated), it does not necessarily have these restrictions.

Since it is assumed for internal stability of MSE walls that $\delta = \beta$, and $\beta$ is assumed to always be zero for internal stability, for a vertical wall, the Coulomb equation simplifies mathematically to the simplest form of the Rankine equation.

All rights reserved. Duplication is a violation of applicable law.

$$k_a = \tan^2\left(45 - \frac{\phi'_f}{2}\right) \qquad \text{(C11.10.6.2.1c-1)}$$

If the wall face is battered, the following simplified form of the Coulomb equation may be used for the Coherent Gravity Method:

$$k_a = \frac{\sin^2\left(\theta + \phi'_f\right)}{\sin^3\theta\left(1 + \frac{\sin\phi'_f}{\sin\theta}\right)^2} \qquad \text{(C11.10.6.2.1c-2)}$$

with variables as defined in Figure 3.11.5.3-1.

*11.10.6.2.1d—Coherent Gravity Method*

The Coherent Gravity Method shall be applied to inextensible (e.g., steel) soil reinforcement systems. The Coherent Gravity Method should be not used for walls with cohesive backfill (i.e., soil with a plastic index greater than 6).

For steel-reinforced wall systems, the lateral earth pressure coefficient used shall be equal to $k_o$ at the point of intersection of the theoretical failure surface with the ground surface at or above the wall top, transitioning to $k_a$ at a depth of 20.0 ft below that intersection point, and constant at $k_a$ at depths greater than 20.0 ft as illustrated in Figure 11.10.6.2.1d-1.

For the Coherent Gravity Method, the reinforced wall mass is treated as a rigid body. Vertical stress shall be calculated at each reinforcement level using an equivalent uniform pressure that accounts for load eccentricity caused by the lateral earth pressure acting at the back of the reinforced soil mass above the reinforcement level being considered. This base pressure shall be applied over an effective width of reinforced wall mass as shown in Figure 11.10.6.2.1d-2. Live load should not be included in the vertical stress calculation to determine $T_{max}$ for assessing pullout loads when using the Coherent Gravity Method, but live load is included in the vertical stress calculation for assessing the needed reinforcement strength.

The calculation of $T_{max}$ using the Coherent Gravity Method is summarized in Eqs. 11.10.6.2.1d-1 through 11.10.6.2.1d-4, and Figures 11.10.6.2.1d-1 and 11.10.6.2.1d-2, as follows:

$$T_{\max} = S_v k_r \sigma_v \qquad \text{(11.10.6.2.1d-1)}$$

$$\sigma_v = \frac{V_1 + V_2 + F_T \sin\beta}{L - 2e} \qquad \text{(11.10.6.2.1d-2)}$$

*C11.10.6.2.1d*

See Allen, et al. (2001) for additional information regarding the Coherent Gravity Method, including comparisons to measured reinforcement loads and vertical stresses in a number of instrumented full-scale walls. See NCHRP Report 290 (Mitchell and Villet, 1987) for some example problems using this method.

For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

All rights reserved. Duplication is a violation of applicable law.

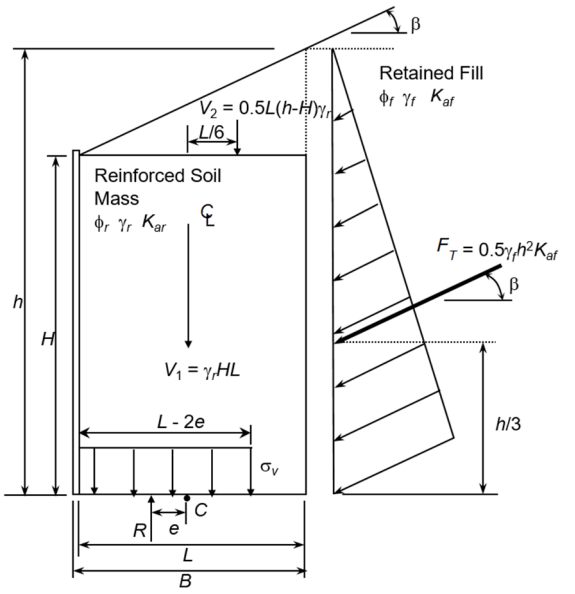

**Figure 11.10.6.2.1d-2—Forces and stresses for Calculating Meyerhof Vertical Stress Distribution in MSE Walls**

For more complex MSE wall loading situations, reinforcement loads shall be calculated as specified in Articles 11.10.10 and 11.10.11, accounting for the eccentricity of each load and its effect on $T_{max}$ for each layer.

*11.10.6.2.1e—Stiffness Method*

The Stiffness Method shall be applied to extensible (e.g., geosynthetics such as geotextiles, geogrids, and geostrips) soil reinforcement in MSE systems. Prevention of soil failure (Service Limit State) as specified in Article 11.10.4.3 shall be assessed when using this method.

$T_{max}$ shall be determined as follows using the Stiffness Method:

$$T_{\max} = S_v \left[ H\gamma_r D_{t\max} + \gamma_f \left( \frac{H_{ref}}{H} \right) S \right] k_{avh} \Phi \qquad (11.10.6.2.1e\text{-}1)$$

where:

$S_v$ = tributary vertical thickness for reinforcement layer (ft)
$H$ = height of wall (ft)
$H_{ref}$ = reference wall height = 20.0 ft
$\gamma_r$ = unit weight of soil in wall reinforcement zone (lbs/ft$^3$)
$S$ = average soil surcharge thickness over reinforcement (ft)
$\gamma_f$ = unit weight of soil in wall in surcharge above wall (kips/ft$^3$)
$D_{tmax}$ = $T_{max}$ distribution factor (dim.)

*C11.10.6.2.1e*

As is true of the Coherent Gravity Method, the Stiffness Method was developed empirically to estimate MSE wall soil reinforcement loads at operational conditions. Therefore, it is necessary to make sure that the strains in the reinforcement are not large enough to allow a shear surface to fully develop through the reinforced wall backfill. Since the Stiffness Method, especially for relatively extensible soil reinforcement, provides a less conservative estimate of reinforcement loads, ensuring that the soil failure (Service Limit State) is not reached or exceeded as specified in Article 11.10.4.3 is an important component of this method.

For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

This method does not calculate the vertical stress at each reinforcement level as is done in the Coherent Gravity (Article 11.10.6.2.1d) and Simplified (Appendix B11) methods. Instead, the vertical stress at the base of the wall is calculated (i.e., equal to $H\gamma_r$ if no soil surcharge is present), multiplied by $k_{avh}$ using Eq. C11.10.6.2.1c-1, and is distributed to each reinforcement layer using an empirical $T_{max}$ distribution factor, $D_{tmax}$. Note that the facing batter is not taken into account using the active earth pressure coefficient directly, but instead is taken into account through the facing batter factor. Additional loads in the reinforcement, such as due to a sloping soil

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$k_{avh}$ = active earth pressure coefficient for a wall with a vertical face (dim.)
$\Phi$ = empirically determined influence factor that captures the effect that the soil reinforcement properties, soil cohesion, and wall geometry have on $T_{max}$ (dim.)

$D_{tmax}$ shall be determined as follows:

For $z < z_b$:

$$D_{t\max} = D_{t\max 0} + \left(\frac{z}{z_b}\right)\left(1 - D_{t\max 0}\right) \quad (11.10.6.2.1e\text{-}2)$$

For $z \geq z_b$: $D_{tmax} = 1.0$

$$z_b = C_h\left(H\right)^{1.2} \quad (11.10.6.2.1e\text{-}3)$$

where:

$z$ = depth of reinforcement layer below top of wall at wall face (ft)
$z_b$ = depth below top of wall at wall face where $D_{tmax}$ becomes equal to 1.0 (and below which $D_{tmax}$ equals 1.0) (ft)
$D_{tmax0}$ = $T_{max}$ distribution factor magnitude at top of wall at wall face, equal to 0.12 (dim.)
$C_h$ = coefficient equal to 0.32 when $H$ is in ft and 0.40 when $H$ is in meters

For vertical or near-vertical walls (i.e., a facing batter of 10 degrees or less from the vertical) with a single reinforcement strength and stiffness, and cohesionless backfill soil (defined as having a plasticity index of 6 or less), $\Phi$ shall be determined as follows:

$$\Phi = \Phi_g \Phi_{fs} \quad (11.10.6.2.1e\text{-}4)$$

where:

$\Phi_g$ = global stiffness factor (dim.)
$\Phi_{fs}$ = facing stiffness factor

The global stiffness factor shall be determined as follows:

$$\Phi_g = 0.16\left(\frac{S_{global}}{P_a}\right)^{0.26} \quad (11.10.6.2.1e\text{-}5)$$

where:

$S_{global}$ = global reinforcement stiffness (ksf)
$P_a$ = atmospheric pressure at sea level (equals 2.11 ksf)

and,

surcharge, are added to each reinforcement layer using a superposition principle. For a sloping or broken back soil surcharge above the wall, the average surcharge height, $S$, as defined in Article 11.10.6.2.1 is multiplied by the soil surcharge unit weight, and is then adjusted for its influence on $T_{max}$ based on $H_{ref}/H$. This adjustment is greater than 1.0 if the wall height is less than $H_{ref}$ (i.e., short stubby walls) and is less than 1.0 for taller walls. Hence, the taller the wall, the less the soil surcharge influences the $T_{max}$ values. For concentrated surcharge loads such as due to a structure footing, using superposition, Articles 3.11.6.3, 3.11.6.4, 11.10.10, and 11.10.11 apply, in which the additional lateral stress over the reinforcement layer tributary area is conservatively added directly to $T_{max}$. Similarly, for seismic loads for internal stability design, Article 11.10.7.2 applies, in which the additional lateral stress over the tributary area for each reinforcement layer or element is conservatively added directly to $T_{max}$ by superposition.

Determination of the $T_{max}$ distribution factor, $D_{tmax}$, is illustrated in Figure C11.10.6.2.1e-1. In the figure, depths below the wall top have been normalized by the wall height, $H$. $T_{mxmx}$ is the maximum value of $T_{max}$ in the wall section.

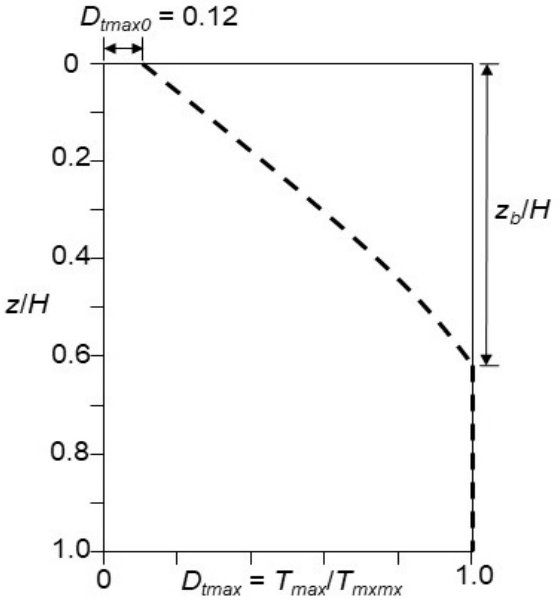

**Figure C11.10.6.2.1e-1—Illustration of $D_{tmax}$ Factor**

Eqs. 11.10.6.2.1e-1 through 11.10.6.2.1e-6 are a simplified version of the complete Stiffness Method. The complete Stiffness Method contains additional influence factors to account for facing batter, $\Phi_{fb}$, variations in the stiffness of the reinforcement within the wall cross-section, $\Phi_{local}$, and soil cohesion, $\Phi_c$. The complete Stiffness Method and its application to MSE wall internal stability design is provided in Allen and Bathurst (2015, 2018). The Supplemental Materials for Allen and Bathurst (2018) also include detailed step-by-step procedures and

$$S_{global} = \frac{J_{ave}}{(H/n)} = \frac{\sum_{i=1}^{n} J_i}{H} \qquad (11.10.6.2.1e\text{-}6)$$

where:

$J_{ave}$ = average secant tensile stiffness of all $n$ reinforcement layers (kips/ft)
$J_i$ = secant tensile stiffness of reinforcement layer i considering the horizontal spacing, i.e., the coverage ratio $R_c$, of the reinforcement (kips/ft)
$n$ = number of reinforcement layers in wall section (dim.)

For discontinuous reinforcement, the reinforcement coverage ratio shall be determined as specified in Article 11.10.6.4.1.

For geogrids and geotextiles, the reinforcement stiffness should be based on the laboratory secant creep stiffness at 2 percent strain and 1,000 hours as specified in AASHTO R 69.

For a flexible faced wall with extensible reinforcement (e.g., geosynthetics), set $\Phi_{fs} = 1$.

If the wall is tall enough such that layers with different strength and stiffness properties are needed to match the layer strengths to the layer specific $T_{max}$ values, the complete Stiffness Method equation described in Article C11.10.6.2.1 should be used.

If the MSE wall internal stability design using this method results in the reinforcement strength required to be near or below the strength of the weakest geosynthetic reinforcement products available, the maximum reinforcement spacing requirements, both in the vertical and horizontal direction, specified in Articles 11.10.2.3.1 and 11.10.6.2.1b, and the minimum installation damage resistance specified in Article 11.10.6.4.2b, shall still be met.

examples of how to use the method for LRFD internal stability design of MSE walls. The complete method should be used if the wall face is significantly battered or stepped (i.e., a facing batter of 10 degrees or more from the vertical), for geosynthetic walls in which the wall facing is flexible and the reinforcement layer stiffness values vary significantly within the wall section, and for walls which have a stiff facing.

It is assumed that the wall backfill meeting the requirements in Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications* is noncohesive (i.e., *PI* less than or equal to 6 and a fines content of less than 15 percent). If any cohesion is present for soil that meets these *PI* and percent fines content requirements, it should be assumed that this cohesion will be lost at some point during the wall design life. Since no cohesion is assumed for determination of $T_{max}$, the cohesion influence factor, $\Phi_c$, in the complete Stiffness Method in Allen and Bathurst (2015 and 2018) should be assumed equal to 1.0. See Allen and Bathurst (2018) for additional guidance regarding the effect of long-term changes in soil cohesion and its potential post-construction effect on wall face deformation and reinforcement loading.

For geostrip walls, working strains tend to be lower than for other geosynthetics based on strain measurements observed in full scale geostrip walls (Miyata et al., 2018), and $J_i$ determined at a strain level of 1 percent may be more appropriate.

A comparison between the Simplified Method and the complete Stiffness Method, not including traffic surcharge load, is provided in Figure C11.10.6.2.1e-2. Essentially, the Stiffness Method was developed by starting with the Simplified Method, correcting the $T_{max}$ distribution to more accurately reflect measurements in full-scale structures, and replacing the semi-empirical ($k_r/k_a$) term with a reinforcement stiffness-based term calibrated to measurements in full-scale structures.

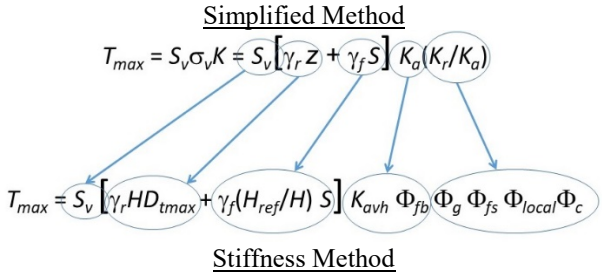

**Figure C11.10.6.2.1e-2—Comparison of AASHTO Simplified and Stiffness Method Equations (Allen and Bathurst 2015)**

Facing stiffness factor, $\Phi_{fs}$, could also be conservatively set to 1.0 for tall geosynthetic walls (i.e., $H > 10$ m) and for typical "thin" panel-face systems, such as incremental concrete panels. For geosynthetic reinforcement and a stiff facing, $\Phi_{fs}$ should be determined as described in Allen and Bathurst (2015 and 2018).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Alternatively, $\Phi_{fs}$ in that case may conservatively be assumed to be equal to 1.0.

For full height and incremental panel walls, $h_{eff} = H$ and panel height, respectively. Since the facing stiffness factor, $\Phi_{fs}$, is intended to be a single value for the wall, a single representative value of $h_{eff}$ must be selected. Typically, $h_{eff}$ is set equal to the reinforcement vertical spacing in modular block-type structures since the reinforcement is located at the horizontal joints between facing units. For blocks that do not have a reinforcement layer at the horizontal joints, these facings will have better interlock and moment transfer from block to block. If the reinforcement spacing is nonuniform, the smallest predominate spacing should be used for this calculation. Smaller $h_{eff}$ values will lead to more conservative design because the facing stiffness factor will be larger. For two-stage walls in which the outer facing is built after the wall is built to full height, the facing stiffness factor should be based on the facing stiffness of the first stage wall (typically the first stage wall face is flexible, and the facing stiffness factor is 1.0 in that case).

It is possible that, especially for shorter walls, the strength required using this method could be at or below the weakest geosynthetic reinforcement products available. In such cases it is important to:

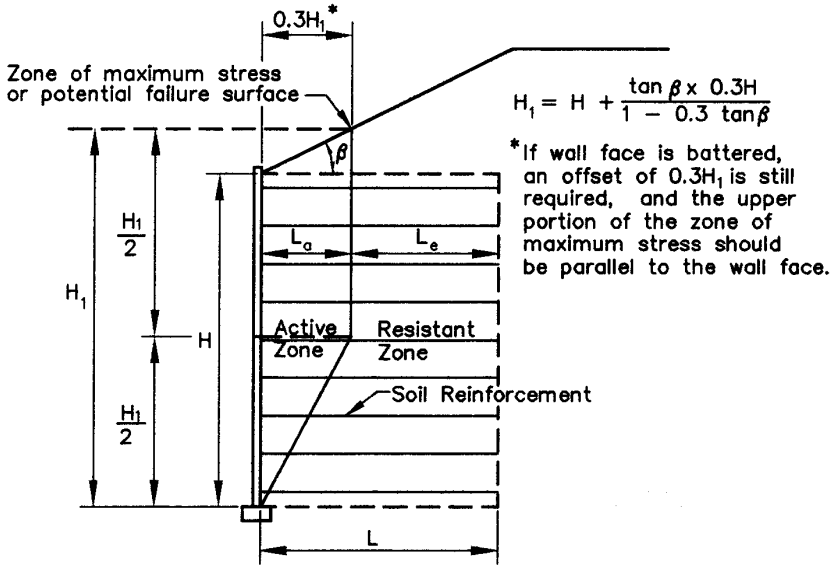
- keep the reinforcement spacing, both vertically and horizontally, within the maximum limits specified in Articles 11.10.2.3.1 and C11.10.6.2.1b;
- keep the reinforcement strong enough such that installation damage does not become excessive, as defined in Article 11.10.6.4.2b and C11.10.6.4.2b.

In such cases it may be necessary to use reinforcement that is stronger than the minimum strength required when using this $T_{max}$ prediction method.

*11.10.6.2.2—Reinforcement Loads at Connection to Wall Face*

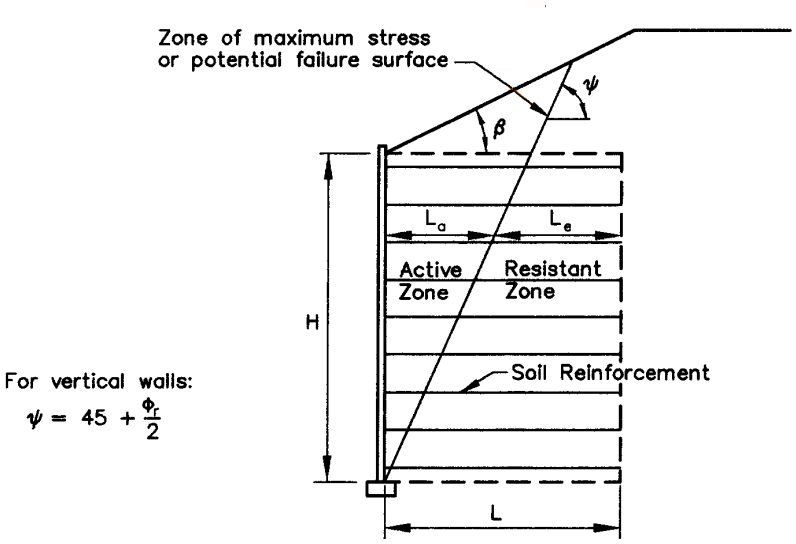
The nominal tensile load applied to the soil reinforcement connection at the wall face, $T_o$, shall be equal to the nominal reinforcement tension, $T_{max}$, for all wall systems regardless of facing and reinforcement type.

**11.10.6.3—Reinforcement Pullout**



*11.10.6.3.1—Boundary between Active and Resistant Zones*

The location of the zone of maximum stress for inextensible and extensible wall systems, i.e., the boundary between the active and resistant zones, is determined as shown in Figure 11.10.6.3.1-1. For all wall systems, the zone of maximum stress shall be assumed to begin at the back of the facing elements at the toe of the wall.



For extensible wall systems with a face batter of less than ten degrees from the vertical, the zone of maximum

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

stress should be determined using the Rankine method. Since the Rankine method cannot account for wall face batter or the effect of concentrated surcharge loads above the reinforced backfill zone, the Coulomb method shall be used for walls with extensible reinforcement in cases of significant batter, defined as ten degrees from vertical or more, and concentrated surcharge loads to determine the location of the zone of maximum stress.

**(a) Inextensible Reinforcements**

For walls with a face batter 10 degrees or more from the vertical,

$$\tan\left(\Psi-\phi_r\right)=\frac{-\tan\left(\phi_r-\beta\right)+\sqrt{\tan\left(\phi_r-\beta\right)\left[\tan\left(\phi_r-\beta\right)+\cot\left(\phi_r+\theta-90\right)\right]\left[1+\tan\left(\delta+90-\theta\right)\cot\left(\phi_r+\theta-90\right)\right]}}{1+\tan\left(\delta+90-\theta\right)\left[\tan\left(\phi_r-\beta\right)+\cot\left(\phi_r+\theta-90\right)\right]}$$

with $\delta = \beta$ and all other variables defined in Figure 3.11.5.3-1.

**(b) Extensible Reinforcements**

**Figure 11.10.6.3.1-1—Location of Potential Failure Surface for Internal Stability Design of MSE Walls**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*11.10.6.3.2—Reinforcement Pullout Design*

The reinforcement pullout resistance shall be checked at each level against pullout failure. Only the effective pullout length which extends beyond the theoretical failure surfaces in Figure 11.10.6.3.1-1 shall be used in this calculation. A minimum length, $L_e$, in the resistant zone of 3.0 ft shall be used. The total length of reinforcement required for pullout is equal to $L_a + L_e$ as shown in Figure 11.10.6.3.1-1.

Note that traffic loads applied as a uniform surcharge are neglected in pullout calculations (see Figure 11.10.6.2.1a-2). Lateral traffic impact loads, such as through a traffic barrier, however, should not be neglected.

The effective pullout length shall be determined using the following equation:

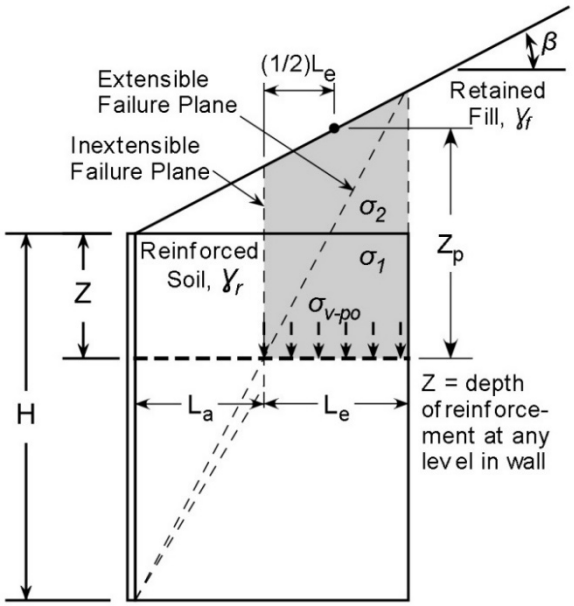
$$L_e \geq \frac{\gamma_{p-EV} T_{max}}{\phi F^* \alpha \sigma_v C R_c} \qquad (11.10.6.3.2\text{-}1)$$

where:

$L_e$ = length of reinforcement in resisting zone (ft)
$T_{max}$ = applied load in the reinforcement from Article 11.10.6.2.1 (kips/ft)
$\gamma_{p\text{-}EV}$ = load factor for vertical earth pressure specified in Table 3.4.1-2 (dim.)
$\phi$ = resistance factor for reinforcement pullout from Table 11.5.7-1 (dim.)
$F^*$ = pullout friction factor (dim.)
$\alpha$ = scale effect correction factor (dim.)
$\sigma_v$ = unfactored vertical stress at the reinforcement level in the resistant zone (ksf)
$C$ = overall reinforcement surface area geometry factor based on the gross perimeter of the reinforcement and is equal to 2 for strip, grid and sheet-type reinforcements, i.e., two sides (dim.)
$R_c$ = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)

The vertical stress, $\sigma_v$, used to calculate pullout resistance shall be determined as shown in Figure 11.10.6.2.1a-2 for the horizontal backslope condition and in Figure 11.10.6.3.2-1 for the sloping backslope condition.

For more complex loading situations, such as due to the presence of traffic impact load or concentrated loads due to foundations located on top of or within the reinforced soil, Eq. 11.10.6.3.2-1 shall be modified to accommodate the load combination, replacing $\gamma_{p\text{-}EV} T_{max}$ with $T_{totalf}$ as calculated in Eq. 11.10.10.1-1, when concentrated foundation loads are present. When traffic impact loads (i.e., as applied through a traffic barrier) are



*C11.10.6.3.2*

$F^*\alpha\sigma_v C L_e$ is the ultimate pullout resistance, $P_r$, per unit of reinforcement width.

Since the traffic impact load is applied near the back of the wall face, the full length of the reinforcement behind the wall face could be used to calculate pullout resistance to the load increase caused by the impact load, as recommended by Bligh, et al. (2010).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

present, pullout design shall include the additional transient load as specified in Article 11.10.10.2.

Nominal Vertical Confining Pressure :

$\sigma_1 = \gamma_r Z$

$\sigma_2 = \gamma_f (Z_p - Z)$ for sloping backfill

$\sigma_{v-po} = \gamma_r Z + \gamma_f \left( Z_p - Z \right)$

$Z_p = Z + \left( L_a + \left( \frac{1}{2} \right) L_e \right) \tan \beta$ for sloping backfill

**Figure 11.10.6.3.2-1—Vertical Confining Pressure and $Z_p$ Depth in Resistant Zone beneath Sloping Backfill**

*F** and α shall be determined from product-specific pullout tests in the project backfill material or equivalent soil, or they can be estimated empirically/theoretically.

For standard backfill materials (see *AASHTO LRFD Bridge Construction Specifications,* Article 7.3.6.3), with the exception of uniform sands, i.e., coefficient of uniformity $C_u = D_{60}/D_{10} < 4$, in the absence of test data it is acceptable to use conservative default values for *F** and α as shown in Figure 11.10.6.3.2-2 and Table 11.10.6.3.2-1. For ribbed steel strips, if the specific $C_u$ for the wall backfill is unknown at the time of design, a $C_u$ of 4.0 should be assumed for design to determine *F**.

**Table 11.10.6.3.2-1—Default Values for the Scale Effect Correction Factor, α**

| Reinforcement Type | Default Value for α |
|---|---|
| All Steel Reinforcements | 1.0 |
| Geogrids and Geostrips | 0.8 |
| Geotextiles | 0.6 |

Pullout testing and interpretation procedures (and direct shear testing for some parameters), as well as typical empirical data, are provided in Appendix B of FHWA-NHI-10-025 (Berg et al., 2009).

Recent experience with pullout test results on new geogrids coming into the market has indicated that some materials have pullout values that are lower than the previous *F** default value of 0.8 tan ϕ. Data obtained by D'Appolonia (1999) also indicate that 0.8 tan ϕ is closer to a mean value rather than a default lower bound value for geogrids. The default values for other reinforcement types shown in Figure 11.10.6.3.2-2 are more representative of lower bound values. Therefore, the *F** default value for geosynthetics, including geogrids, geotextiles, and geostrips, has thus been lowered to a more conservative value of 0.67 tan ϕ in consideration of these results.

Product-specific pullout testing, if conducted, may not necessarily result in lower bound values of *F** and α. In this case, the resistance factors for pullout specified in Table 11.5.7-1 may need to be reduced to provide the same level of safety implied by the specified resistance factors and default lower bound pullout parameters.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The scale effect correction factor $\alpha$ shall be no greater than 1.0.

For grids, the spacing between transverse grid elements, $S_t$, shall be uniform throughout the length of the reinforcement rather than having transverse grid members concentrated only in the resistant zone.

For $F^*$ values based on product- and soil-specific test data, the value of $F^*$ at a depth of 20.0 ft or more should be limited to tan $\phi_r$, unless the reinforcement geometry can provide significant passive resistance in addition to interface shear. To assess the potential for significant passive resistance during product- and soil-specific pullout testing, the maximum displacement should be limited to 0.75 in. to determine $F^*$.

$F^*$ for ladder strips, defined as a combination of longitudinal and transverse wires welded together to form a reinforcement strip structure of limited width resembling a ladder, should be determined through product-specific testing. Ladder strips can behave in much the same way as ribbed steel strips if the spacing of the transverse wires or bars is sufficiently frequent. For greater transverse wire or bar spacing, the behavior of ladder strips may instead resemble steel grids. Product-specific testing is needed to determine how the ladder strip behaves in pullout. Regarding the effective width of ladder strips, the entire length of the transverse wire or bar may contribute to the pullout resistance, depending on the length of the protrusions beyond the longitudinal members and the stiffness of the protrusions. This also should be verified through product-specific testing.

For the case when geogrids are cut into strips, the portion of the transverse geogrid members that protrude beyond the outside longitudinal members in the strip should not be considered to contribute to the effective reinforcement width and pullout resistance, due to the flexibility of the transverse geogrid elements.

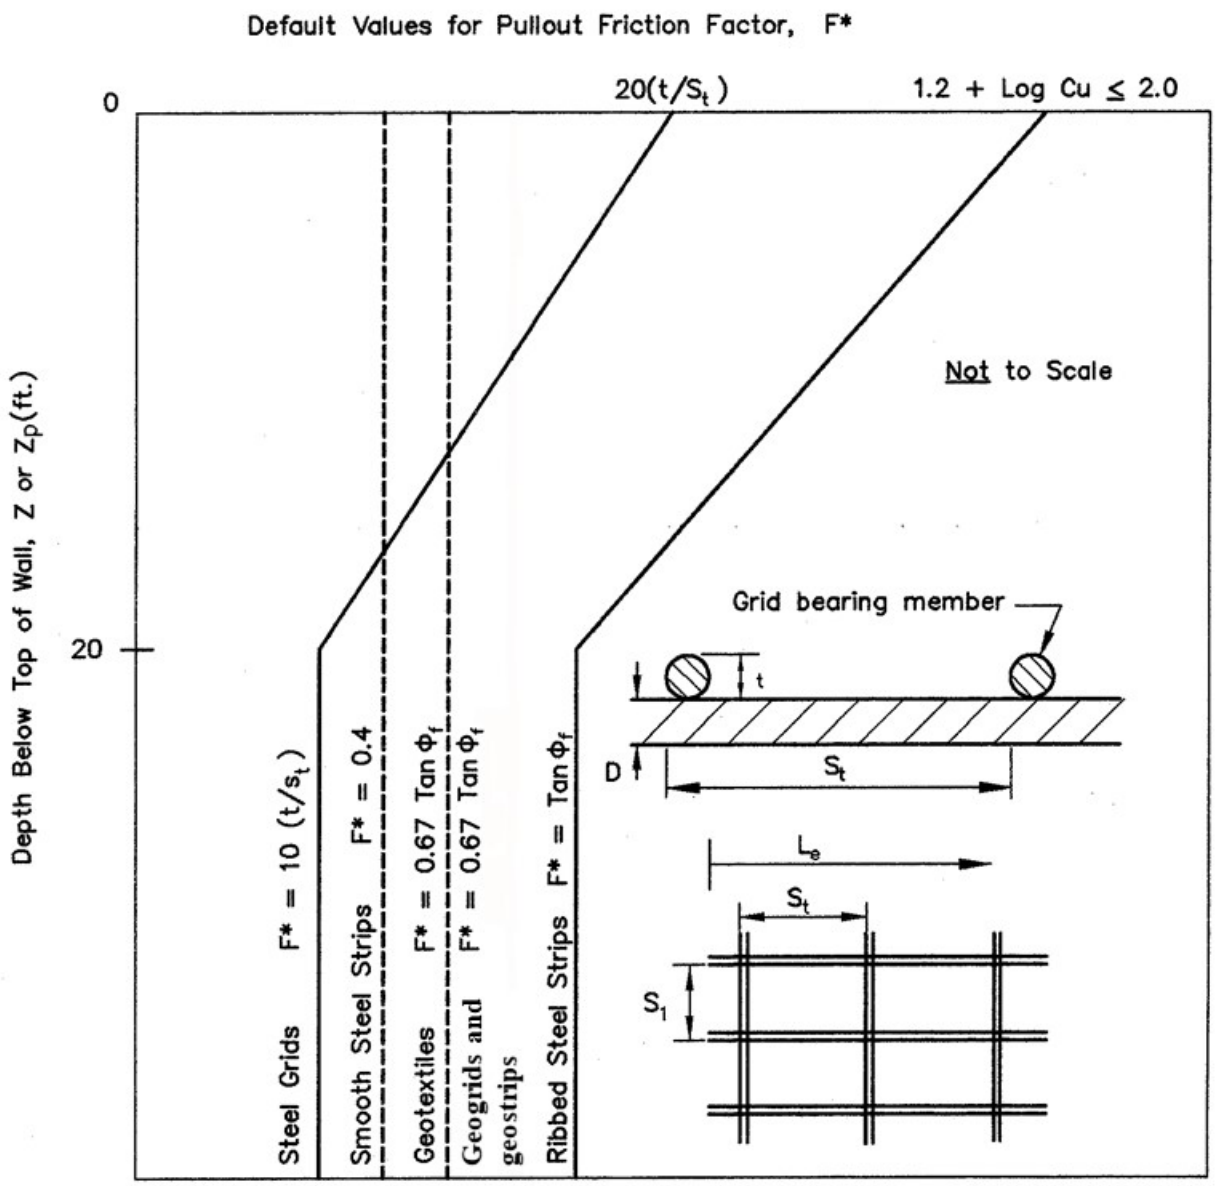

**Figure 11.10.6.3.2-2—Default Values for the Pullout Friction Factor, *F**

These pullout calculations assume that the factored long-term strength of the reinforcement (see Article 11.10.6.4.1) in the resistant zone is greater than $T_{max}$.

### 11.10.6.4—Reinforcement Strength

*11.10.6.4.1—General*

*C11.10.6.4.1*

The reinforcement strength shall be checked at every level within the wall, both at the boundary between the active and resistant zones (i.e., zone of maximum stress), and at the connection of the reinforcement to the wall face, for applicable strength limit states as follows:

At the zone of maximum stress:

The load factor, $\gamma_{EV}$, should be applied to the calculated value of $T_{max}$. This applies to all methods used to calculate $T_{max}$ with regard to soil self-weight of the reinforced soil volume, as well as soil surcharges (sloping or level) placed above the reinforced soil volume.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$\gamma_{p-EV} T_{\max} \le \phi T_{al} R_c \qquad (11.10.6.4.1\text{-}1)$$

where:

$T_{max}$ = applied load to the reinforcement determined as specified in Article 11.10.6.2.1 (kips/ft)
$\gamma_{p\text{-}EV}$ = load factor for vertical earth pressure specified in Table 3.4.1-2 (dim.)
$\phi$ = resistance factor for reinforcement tension, specified in Table 11.5.7-1 (dim.)
$T_{a\ell}$ = nominal long-term reinforcement strength (kips/ft)
$R_c$ = reinforcement coverage ratio as defined in Figures 11.10.6.4.1-1 and 11.10.6.4.1-2 (dim.)

$T_{a\ell}$ shall be determined as specified in Article 11.10.6.4.3a for steel reinforcement and Article 11.10.6.4.3b for geosynthetic reinforcement.

When live load is present and treated as an additional uniform surcharge as specified in Article 3.11.6.4, the difference in the load factor used for live load surcharge, *LS*, versus that used for the self-weight of the reinforced backfill, *EV*, shall be recognized when applying load factors to $T_{max}$ to determine the factored reinforcement load.

In past design practice, live load surcharge (load factor is $\gamma_{LS}$) is usually included in the calculation of the vertical stress acting at the reinforcement level as a uniform soil surcharge. However, since the load factor applied to *LS* is different in magnitude than the load factor applied to soil self-weight (i.e., 1.75 versus 1.35, respectively), the live load surcharge contribution to $T_{max}$ is calculated and factored separately from the soil self-weight contribution to $T_{max}$.

For more complex loading situations, such as due to the presence of concentrated loads due to foundations located on top of or within the reinforced soil and traffic barrier impact forces, determine $T_{max}$ as specified in Article 11.10.10. Eq. 11.10.6.4.1-1 shall be modified to accommodate the load combination using superposition, replacing $\gamma_{p\text{-}EV} T_{max}$ with $T_{totalf}$ as calculated in Eq. 11.10.10.1-1. When traffic impact loads (i.e., as applied through a traffic barrier) are present, reinforcement strength design shall include the additional transient load as specified in Article 11.10.10.2.

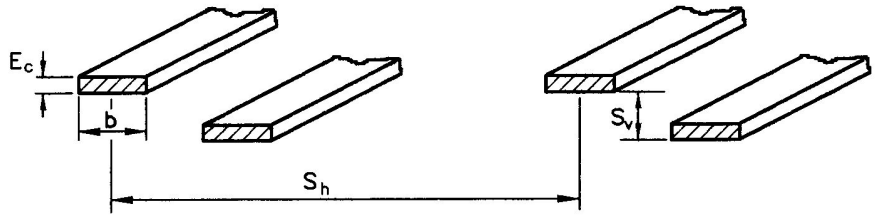
At the connection with the wall face:

$$\gamma_{p-EV} T_o \le \phi T_{ac} R_c \qquad (11.10.6.4.1\text{-}2)$$

where:

$T_o$ = applied load at reinforcement/facing connection specified in Article 11.10.6.2.2 (kips/ft)
$\gamma_{p\text{-}EV}$ = load factor for vertical earth pressure specified in Table 3.4.1-2 (dim.)
$\phi$ = resistance factor for reinforcement tension in connectors specified in Table 11.5.7-1 (dim.)
$T_{ac}$ = nominal long-term reinforcement/facing connection strength (kips/ft)

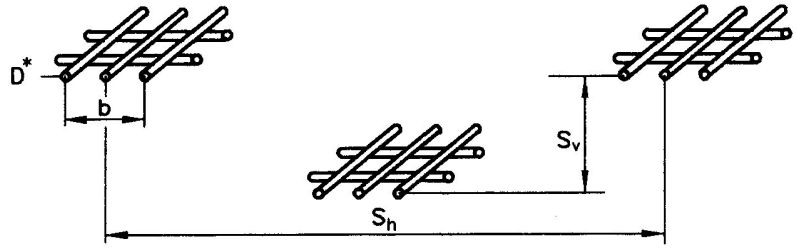
© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.



$R_c$ = reinforcement coverage ratio as defined in Figures 11.10.6.4.1-1 and 11.10.6.4.1-2 (dim.)

For more complex loading situations, such as due to the presence of traffic impact load or concentrated loads due to foundations located on top of or within the reinforced soil, Eq. 11.10.6.4.1-2 shall be modified to accommodate the load combination, replacing $\gamma_{p\text{-}EV}T_o$ with $T_{totalof}$, the factored connection load, in which $T_{totalof}$ is as calculated in Eq. 11.10.10.1-2, when concentrated foundation loads are present.

$T_{ac}$ shall be determined at the wall face connection as specified in Article 11.10.6.4.4a for steel reinforcement and Article 11.10.6.4.4b for geosynthetic reinforcement. The difference in the environment occurring immediately behind the wall face relative to the environment within the reinforcement backfill zone and its effect on the long-term durability of the reinforcement/connection shall be considered when determining $T_{ac}$.



$T_{a\ell}$ shall be determined on a long-term strength per unit of reinforcement width basis and multiplied by the reinforcement coverage ratio, $R_c$, so that it can be directly compared to $T_{max}$ which is determined on a load per unit of wall width basis (this also applies to $T_{ac}$ and $T_o$). For discrete, i.e., not continuous, reinforcements, such as steel strips or bar mats, the strength of the reinforcement is converted to a strength per unit of wall width basis as shown in Figures 11.10.6.4.1-1 and 11.10.6.4.1-2. For continuous reinforcement layers, $b = 1$ and $R_c = 1$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$A_c = bE_c$

$E_c$ = strip thickness corrected for corrosion loss.

$A_c$ = (No. of longitudinal bars) $\left(\pi \frac{D^{*2}}{4}\right)$

$D^*$ = diameter of bar or wire corrected for corrosion loss.

b = unit width of reinforcement (if reinforcement is continuous count number of bars for reinforcement width of 1 unit).

$R_c$ = reinforcement coverage ratio = $\frac{b}{S_h}$

Use $R_c = 1$ for continuous reinforcement (i.e., $S_h = b = 1$ unit width).

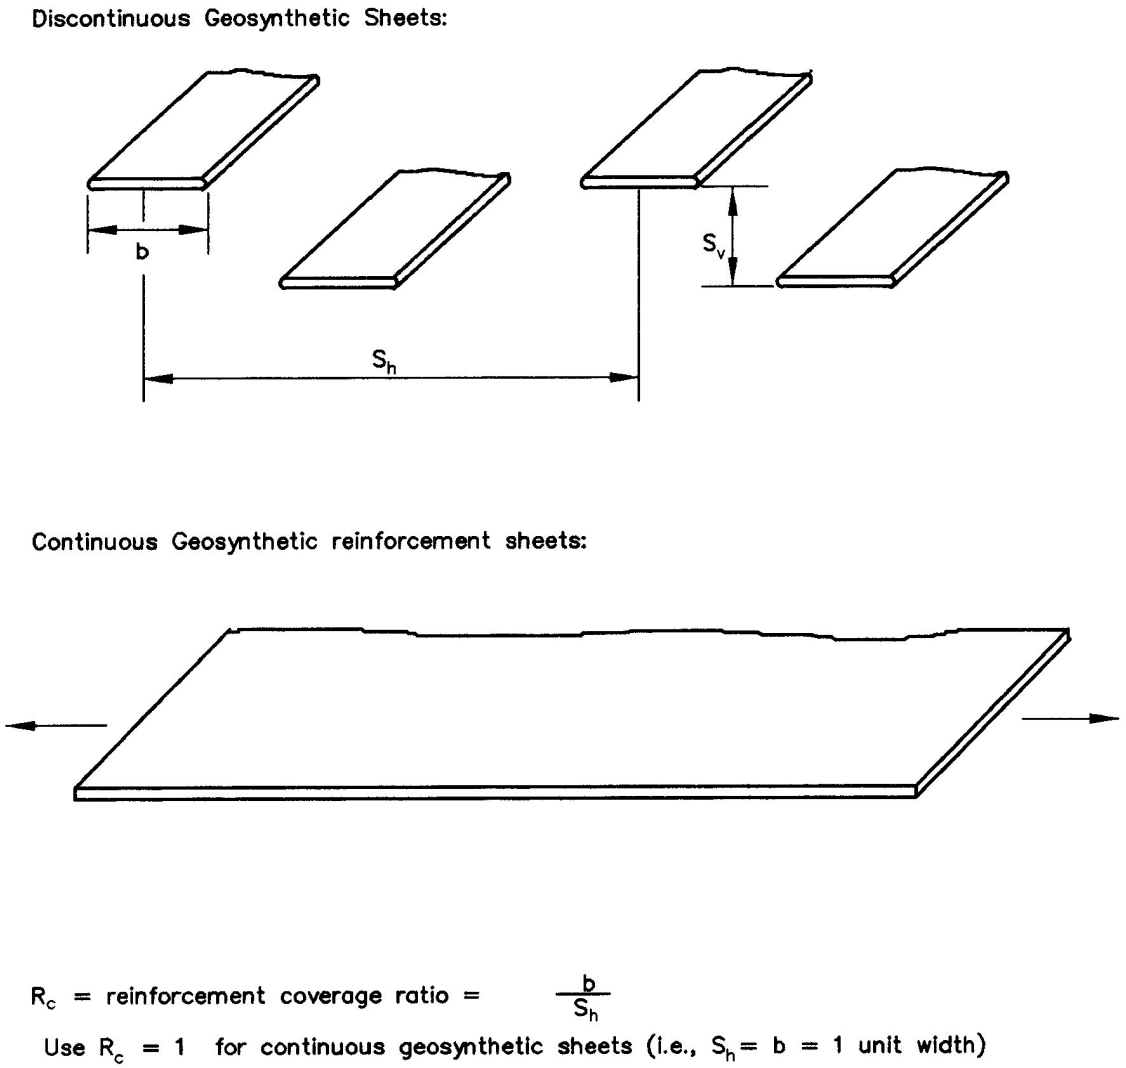

**Figure 11.10.6.4.1-2—Reinforcement Coverage Ratio for Geosynthetic Reinforcement**

*11.10.6.4.2—Design Life Considerations*

The provisions of Article 11.5.1 shall apply.

*11.10.6.4.2a—Steel Reinforcements*

Steel soil reinforcements shall comply with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Article 7.6.4.2, "Steel Reinforcements."

The structural design of steel soil reinforcements and connections shall be made on the basis of a thickness, $E_c$, as follows:

$$E_c = E_n - E_s \qquad (11.10.6.4.2a\text{-}1)$$

where:

$E_c$ = thickness of metal reinforcement at end of service life as shown in Figure 11.10.6.4.1-1 (mil.)
$E_n$ = nominal thickness of steel reinforcement at construction (mil.)

*C11.10.6.4.2a*

Corrosion loss rates summarized in Elias et al. (2009) and Fishman and Withiam (2011) and supplemented by field data developed under other FHWA research studies have been used to establish the sacrificial thicknesses herein.

The backfill specifications contained in *AASHTO LRFD Bridge Construction Specifications*, Section 7, for MSE structures using steel reinforcements present minimum electrochemical requirements, which will generally ensure a mild to moderate potential for corrosion. Where deicing salts are used, adequate drainage provisions for salt laden runoff are required. In some cases, an impervious membrane may be required between the pavement structure and the select backfill. Criteria for evaluating potential corrosion losses are given in Elias et. al (2009).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$E_s$ = sacrificial thickness of metal expected to be lost by uniform corrosion during service life of structure (mil.)

For structural design, sacrificial thicknesses shall be computed for each exposed surface as follows, assuming that the soil backfill used is nonaggressive:

- Loss of galvanizing = 0.58 mil./yr for first 2 years
  = 0.16 mil./yr for subsequent years
- Loss of carbon steel = 0.47 mil./yr after zinc depletion

These metal loss rates shall be considered applicable to hot-dip galvanized steel and not applicable to black steel or steel coated by any other process. Other carbon steel loss rates shall be used for black steel and for steel coated by any other material or process.

Soils shall typically be considered nonaggressive if they meet the following criteria:

- pH = 5 to 10
- Resistivity ≥ 3000 ohm-cm
- Chlorides ≤ 100 ppm
- Sulfates ≤ 200 ppm
- Organic Content ≤ 1 percent

If the resistivity is greater than or equal to 5000 ohm-cm, the chlorides and sulfates requirements may be waived. For bar mat or grid-type reinforcements, the sacrificial thickness listed above shall be applied to the radius of the wire or bar when computing the cross-sectional area of the steel remaining after corrosion losses.

Transverse and longitudinal grid members shall be sized in accordance with ASTM A185. The transverse wire diameter shall be less than or equal to the longitudinal wire diameter.

Galvanized coatings shall be a minimum of 2 oz/ft$^2$ or 3.4 mils in thickness, applied in conformance to AASHTO M 111M/M 111 (ASTM A123/A123M).

These sacrificial thicknesses account for potential pitting mechanisms and much of the uncertainty due to data scatter, and are considered to be maximum anticipated losses for soils which are defined as nonaggressive.

Recommended test methods for soil chemical property determination include AASHTO T 289 for pH, AASHTO T 288 for resistivity, AASHTO T 291 for chlorides, AASHTO T 290 for sulfates, and AASHTO T 267 for organic content. The organic content limit of 1 percent is based on the total soil fraction.

Resistivity at saturation is the basis for the sacrificial thicknesses specified in this Article. Resistivity should be determined under the most adverse condition (i.e., a saturated state) in order to obtain a resistivity that is independent of seasonal and other variations in soil-moisture content (Elias et al., 2009).

These sacrificial thickness requirements are not applicable for soils which do not meet one or more of the nonaggressive soil criteria. Additionally, these sacrificial thickness requirements are not applicable in applications where:

- the MSE wall will be exposed to a marine or other chloride-rich environment,
- the MSE wall has a metallic or wire mesh facing, or the metallic soil reinforcement is continuous, forming an electrically conductive circuit along the wall length, and the wall will be exposed to stray currents such as from nearby underground power lines or adjacent electric railways,
- the backfill material is aggressive, or
- the galvanizing thickness is less than specified in these guidelines.

Each of these situations creates a special set of conditions which should be specifically analyzed by a corrosion specialist. Alternatively, noncorrosive reinforcing elements can be considered. Furthermore, these corrosion rates do not apply to other metals. The use of alloys such as aluminum and stainless steel is not recommended.

Requiring the transverse wire diameter to be less than or equal to the longitudinal wire diameter will preclude local overstressing of the longitudinal wires.

The specified minimum thickness of 3.4 mils is more stringent than the minimum requirements in AASHTO M 111M/M 111 (ASTM A123/A123M).

Corrosion-resistant coatings should generally be limited to galvanization. Hot-dip galvanization should be applied after fabrication of the reinforcement into its final configuration.

There is insufficient evidence at this time regarding the long-term performance of epoxy coatings for these

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

coatings to be considered equivalent to galvanizing. If epoxy-type coatings are used, they should meet the requirements of ASTM A884 for bar mat and grid reinforcements, or ASTM A775/A775M for strip reinforcements, and have a minimum thickness of 16 mils.

*11.10.6.4.2b—Geosynthetic Reinforcements*

The long-term strength of geosynthetic reinforcement shall be assessed with consideration to strength losses that occur during installation, and long-term losses due to creep and chemical degradation. The long-term strength of the geosynthetic reinforcement as calculated in accordance with Article 11.10.6.4.3b shall be determined in accordance with AASHTO R 69.

*Soil and Related Environmental Requirements:* Environmental conditions within the wall shall be assessed considering soil pH, gradation, plasticity, organic content, and in-ground temperature. These conditions shall be considered to be nonaggressive if the following criteria are met:

- pH, as determined by AASHTO T 289, equals 4.5 to 9 for permanent applications and 3 to 10 for temporary applications,
- Maximum soil particle size is less than 0.75 in., unless full-scale installation damage tests are conducted in accordance with AASHTO R 69 and the reduction factor for installation damage, $RF_{ID}$, is less than or equal to 1.7,
- Soil organic content, as determined by AASHTO T 267 for material finer than the 0.0787 in. (No. 10) sieve ≤1 percent, and
- Design temperature at wall site:

  ≤ 86°F for permanent applications
  ≤ 95°F for temporary applications

Soil backfill not meeting these requirements shall be considered to be aggressive. The environment at the face, in addition to that within the wall backfill, shall be evaluated, especially if the stability of the facing is dependent on the strength of the geosynthetic at the face, i.e., the geosynthetic reinforcement forms the primary connection between the body of the wall and the facing.

The chemical properties of the native soil surrounding the mechanically stabilized soil backfill shall

*C11.10.6.4.2b*

The durability of geosynthetic reinforcement is influenced by environmental factors such as time, temperature, mechanical damage, stress levels and chemical exposure, e.g., oxygen, water, and pH, which are the most common chemical factors. Microbiological attack may also affect certain polymers, although not most polymers used for carrying load in soil reinforcement applications. The effects of these factors on product durability are dependent on the polymer type used, i.e., resin type, grade, additives, and manufacturing process, and the macrostructure of the reinforcement. Not all of these factors will have a significant effect on all geosynthetic products. Therefore, the response of geosynthetic reinforcements to these long-term environmental factors is product-specific.

While soil plasticity is not specifically included in the specified wall environment criteria, soils with significant plasticity are more likely to have properties that could have an adverse effect on the long-term performance of the geosynthetic reinforcement. In general for MSE walls, the *AASHTO LRFD Bridge Construction Specifications*, Article 7.3.6.3, require that MSE wall soil backfill have no more than 15 percent fines and a *PI* as determined by AASHTO T 90 of no more than 6. For backfill soil that does not meet these requirements, soil-specific studies to investigate the effect the soil may have on the long-term performance of the geosynthetic reinforcement should be considered.

See Bathurst, et al. (2011) for additional information on the reason for keeping $RF_{ID}$ at or below 1.7, in which they indicate that when $RF_{ID}$ is greater than 1.7, the variability in the as-installed tensile strength increases significantly. The current resistance factor for reinforcement rupture of geosynthetics may not adequately account for this increased variability.

The effective design temperature is defined as the temperature which is halfway between the average yearly air temperature and the normal daily air temperature for the warmest month at the wall site. Note that for walls which face the sun, it is possible that the temperature immediately behind the facing could be higher than the air temperature. This condition should be considered when assessing the design temperature, especially for wall sites located in warm, sunny climates.

A product- and project-site-specific assessment of the effect aggressive conditions may have on the long-term strength of the geosynthetic reinforcement should be considered if the wall environmental conditions are considered to be aggressive.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

also be considered if there is potential for seepage of groundwater from the native surrounding soils to the mechanically stabilized backfill. If this is the case, the surrounding soils shall also meet the chemical criteria required for the backfill material if the environment is to be considered nonaggressive, or adequate long-term drainage around the geosynthetic reinforced mass shall be provided to ensure that chemically aggressive liquid does not enter into the reinforced backfill.

*Polymer Requirements*: Polymers which are likely to have good resistance to long-term chemical degradation shall be used to minimize the risk of the occurrence of significant long-term degradation. The polymer material requirements provided in Table 11.10.6.4.2b-1 shall be met to ensure good resistance to long-term chemical degradation. In this case, the use of a default chemical durability reduction factor, $RF_D$, of 1.3 as specified in AASHTO R 69 is acceptable, provided the wall backfill environment is determined to be nonaggressive.

If the wall backfill environment is determined to be aggressive as defined in this Article, or if the geosynthetic reinforcement polymer does not meet the requirements in Table 11.10.6.4.2b-1, then product-specific durability studies shall be carried out prior to product use to determine the product-specific long-term strength reduction factor, *RF*. These product-specific studies shall be used to estimate the short-term and long-term effects of the aggressive environmental factors on the strength and deformational characteristics of the geosynthetic reinforcement throughout the reinforcement design life as well as the effect of using a geosynthetic reinforcement polymer that does not meet the requirements of Table 11.10.6.4.2b-1.

The use of a default value of 1.3 for $RF_D$ also presumes that the geosynthetic is not excessively damaged during installation, which could expose more of the geosynthetic surface to ions present in the soil that could cause degradation. This is especially important for coated polyester geogrids and geostrips, as there is at least some reliance on the coating to prevent exposure of the underlying polyester fibers to moisture that could cause hydrolysis and degradation of the fibers. Therefore, it may be important to keep the installation damage reduction factor, $RF_{ID}$, reasonably low (i.e., below 1.7 as specified herein).

More detailed FHWA guidance (Berg et al., 2009) on $RF_D$ indicates that $RF_D$ for PET geogrids, based on the same research results as the default reduction factor of 1.3 for the wider pH range defined to be nonaggressive, can be reduced to 1.15 if the soil backfill pH is between 5 and 8. For high density polyethelyene (HDPE) geogrids, $RF_D$ can be as low as 1.1 based on long-term experience. The PET geogrid $RF_D$ values provided above are also applicable to coated PET geostrip reinforcement. This more detailed guidance provided in the FHWA manual regarding default values for $RF_D$ is acceptable to use provided that the environmental requirements specified in that manual are met.

Guidelines for product-specific studies to determine *RF* are provided in Elias et al. (2009) and AASHTO R 69, which is based on WSDOT Standard Practice T925 (WSDOT, 2009). Independent product-specific data from which *RF* may be determined can be obtained from the AASHTO National Transportation Product Evaluation Program (NTPEP) website.

In Table 11.10.6.4.2b-1, for polyester (PET) products that do not meet a minimum of 50 percent strength retained after 500 hours in the weatherometer (ASTM D4355), such products may still be used if the maximum time of exposure to sunlight is reduced further than specified in the table with owner approval to do so.

The requirements provided in Table 11.10.6.4.2b-1 utilize available index tests and are consistent with AASHTO R 69. These index tests can provide an approximate measure of relative resistance to long-term chemical degradation of geosynthetics. Values selected as minimum criteria to allow use without additional long-term testing are based on values for such properties determined from long-term research reported in the literature. These values are considered indicative of good long-term performance or represent a readily available current standard within the industry that signifies that a

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

product has been enhanced for long-term environmental exposure.

There is little long-term history or even laboratory data regarding the durability of geosynthetics containing a significant percentage of recycled material. Therefore, their potential long-term performance is unknown, and long-term data should be obtained for products with significant recycled material to verify their performance before using them.

The recommended protocol for estimation of the reduction factors for long-term strength loss primarily apply to polypropylene (PP), high density polyethylene (HDPE), and polyester (PET), including other polymers used as coatings for PET geogrids and geostrips (e.g., polyvinyl chloride designated as PVC, or polyethylene). There are other polymers that are sometimes used for the base polymer in geosynthetic reinforcement. The protocols for installation damage and creep are generally applicable to most polymers used in geosynthetic reinforcement. However, the chemical durability index test procedures and criteria provided in Table 11.10.6.4.2b-1, as well as the default $RF_D$ value of 1.3, may not be applicable to these other polymers. In such cases, long-term durability procedures and criteria may need to be developed through long-term testing programs. Therefore, it is important to know the applicability of the available testing protocols and criteria used to determine an appropriate value of $RF_D$ for the geosynthetic reinforcement polymer. In such cases, a detailed evaluation of the geosynthetic reinforcement by organizations such as AASHTO NTPEP is highly recommended.

**Table 11.10.6.4.2b-1—Minimum Requirements for Geosynthetic Products to Allow Use of Default Reduction Factor for Long-Term Degradation**

| Polymer Type | Property | Test Method | Criteria to Allow Use of Default *RF* |
|---|---|---|---|
| Polypropylene (PP) and High Density Polyethylene (HDPE) | UV Oxidation Resistance | ASTM D4355 | Minimum 70% strength retained after 500 hrs. in weatherometer |
| Polyester (PET) | UV Oxidation Resistance | ASTM D4355 | Minimum 50% strength retained after 500 hrs. in weatherometer if geosynthetic will be buried within 1 week, or 70% strength retained if left exposed for more than 1 week |
| Polypropylene | Thermo-Oxidation Resistance | ENV ISO 13438: 2004, Method A | Minimum 50% strength retained after 28 days |
| Polyethylene | Thermo-Oxidation Resistance | ENV ISO 13438: 2004, Method B | Minimum 50% strength retained after 56 days |
| Polyester | Hydrolysis Resistance | Intrinsic Viscosity Method (ASTM D4603) and GRI Test Method GG8, or Determine Directly Using Gel Permeation Chromatography | Minimum Number Average Molecular Weight of 25000 |
| Polyester | Hydrolysis Resistance | ASTM D7409 | Maximum of Carboxyl End Group Content of 30 |
| All Polymers | % Post-Consumer Recycled Material by Weight | Certification of Materials Used | Maximum of 0% |

*11.10.6.4.3—Design Tensile Resistance*

*11.10.6.4.3a—Steel Reinforcements*

The nominal reinforcement tensile resistance is determined by multiplying the yield stress by the cross-sectional area of the steel reinforcement after corrosion losses (see Figure 11.10.6.4.1-1). The loss in steel cross-sectional area due to corrosion shall be determined in accordance with Article 11.10.6.4.2a. The reinforcement tensile resistance shall be determined as:

$$T_{al} = \frac{A_c F_y}{b} \qquad (11.10.6.4.3a\text{-}1)$$

where:

$T_{a\ell}$ = nominal long-term reinforcement design strength (kips/ft)
$F_y$ = minimum yield strength of steel (ksi)
$A_c$ = area of reinforcement corrected for corrosion loss (Figure 11.10.6.4.1-1) (in.$^2$)
$b$ = unit width of reinforcement (Figure 11.10.6.4.1-1) (ft)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*11.10.6.4.3b—Geosynthetic Reinforcements*

*C11.10.6.4.3b*

The nominal long-term reinforcement tensile strength shall be determined as:

$$T_{al} = \frac{T_{ult}}{RF} \quad (11.10.6.4.3b\text{-}1)$$

where:

$$RF = RF_{ID} \times RF_{CR} \times RF_{D} \quad (11.10.6.4.3b\text{-}2)$$

and:

$T_{al}$ = nominal long-term reinforcement design strength (kips/ft)
$T_{ult}$ = minimum average roll value (MARV) ultimate tensile strength (kips/ft)
$RF$ = combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical aging (dim.)
$RF_{ID}$ = strength reduction factor to account for installation damage to reinforcement (dim.)
$RF_{CR}$ = strength reduction factor to prevent long-term creep rupture of reinforcement (dim.)
$RF_{D}$ = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.)

Values for $RF_{ID}$, $RF_{CR}$, and $RF_{D}$ shall be determined from product-specific test results as specified in Article 11.10.6.4.2b. Even with product-specific test results, $RF_{ID}$ shall not be less than 1.05, and $RF_{D}$ shall not be less than 1.1.

$T_{al}$ is the long-term tensile strength required to prevent rupture calculated on a load per unit of reinforcement width basis. $T_{ult}$ is the ultimate tensile strength of the reinforcement determined from wide-width tensile tests specified in ASTM D4595 for geotextiles and ASTM D6637 for geogrids. The value selected for $T_{ult}$ is the minimum average roll value (MARV) for the product to account for statistical variance in the material strength.

$RF_{ID}$, $RF_{CR}$, and $RF_{D}$ are not safety factors, but deterministically reflect the best estimate of actual long-term strength losses that may occur during the specified design life of the geosynthetic. The resistance factor for reinforcement rupture provided in Table 11.5.7-1 is combined with the use of the MARV of $T_{ult}$ to account for the uncertainties in the determination of $T_{al}$.

*11.10.6.4.4—Reinforcement/Facing Connection Design Strength*

*11.10.6.4.4a—Steel Reinforcements*

*C11.10.6.4.4a*

Connections shall be designed to resist reinforcement load at the connection, $T_o$, as calculated in accordance with Articles 11.10.6.4.1 and 11.10.10, as well as from differential movements between the reinforced backfill and the wall facing elements.

Elements of the connection which are embedded in the facing element shall be designed with adequate bond length and bearing area in the concrete to resist the connection forces. The capacity of the embedded connector shall be checked by tests as required in Article 5.10.8.3. Connections between steel reinforcement and the wall facing units, e.g., welds, bolts, pins, etc., shall be designed in accordance with Article 6.13.3.

Connection materials shall be designed to accommodate losses due to corrosion in accordance with Article 11.10.6.4.2a. Potential differences between the environment at the face relative to the environment within

For example, temperature variations may be higher near the face than back in the backfill. Moisture content may also be higher near the back of the wall face than in the wall backfill in general.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

the reinforced soil mass shall be considered when assessing potential corrosion losses.

*11.10.6.4.4b—Geosynthetic Reinforcements*

For connections cast into concrete facing panels, the portion of the connection embedded in the concrete facing shall be designed in accordance with Article 5.10.8.3.

For geosynthetic reinforcement connections that are just behind the facing, or for connections in which the geosynthetic is placed between the facing blocks, the nominal long-term geosynthetic connection strength, $T_{ac}$, on a load per unit reinforcement width basis shall be determined as follows:

$$T_{ac} = \frac{T_{ult} \times CR_{cr}}{RF_D} \qquad (11.10.6.4.4b\text{-}1)$$

where:

$T_{ac}$ = nominal long-term reinforcement/facing connection strength per unit of reinforcement width (kips/ft)
$T_{ult}$ = minimum average roll value (MARV) ultimate tensile strength of soil reinforcement (kips/ft)
$CR_{cr}$ = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)
$RF_D$ = reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (Article 11.10.6.4.3b) (dim.)

If the geosynthetic reinforcement is placed between facing blocks, $T_{ac}$ shall be determined as a function of vertical confining pressure between the facing blocks. Connection tests shall be conducted in accordance with ASTM D6638 to obtain the short-term connection strength, $T_{ultconn}$.

$CR_{cr}$ shall be determined using $RF_{CR}$ to reduce the short-term (i.e., ultimate) connection strength, $T_{ultconn}$, to account for creep of the geosynthetic at the connection, or shall be based on long-term connection creep tests. If connection creep tests are not conducted, $CR_{cr}$ shall be based on short-term connection tests and shall be determined as follows:

$$CR_{cr} = \frac{T_{ultconn}}{\left(RF_{CR} T_{lot}\right)} \qquad (11.10.6.4.4b\text{-}2)$$

where:

$T_{ultconn}$ = nominal short-term connection strength (lbs/ft)
$RF_{CR}$ = strength reduction factor to prevent long-term creep rupture of reinforcement (dim.)

*C11.10.6.4.4b*

The connection test is similar in nature to a wide-width tensile test (ASTM D4595 or ASTM D6637), except that one end of the reinforcement material is sandwiched between two courses of concrete blocks to form one of the grips. This results in the strength of the geosynthetic at the connection being reduced relative to the ultimate wide-width tensile strength. The short-term connection test (ASTM D6638 for segmental concrete block connections) is used to determine the ultimate connection strength, $T_{ultconn}$.

For reinforcements connected to the facing through embedment between facing elements, e.g., segmental concrete block faced walls, the capacity of the connection is conceptually governed by one of two failure modes: rupture, or pullout of the reinforcement. This is consistent with the evaluation of internal wall stability in the reinforced backfill zone, where both the rupture and pullout mode of failure must be considered.

The objective of the connection design is to assess the long-term capacity of the connection. If rupture is the mode of failure, the long-term effects of creep and durability on the geosynthetic reinforcement at the connection, as well as on the connector materials, must be taken into account, as the capacity of the connection is controlled by the reinforcement or connector long-term strength. If pullout is the mode of failure, the capacity of the connection is controlled by the frictional interface between the facing blocks and the geosynthetic reinforcement. It is assumed for design that this interface is not significantly affected by time-dependent mechanisms such as creep or chemical degradation, assuming the pullout resistance available is controlling the connection design.

The load-bearing fibers or ribs of the geosynthetic do not necessarily have to experience rupture in the connection test for the mode of failure to be rupture. If the connector is a material that is susceptible to creep, failure of the connectors between blocks due to creep rupture of the connector could result in long-term connection strength losses. In these cases, the value of $CR_{cr}$ and $RF_D$ to be used in Eq. 11.10.6.4.4b-1 should be based on the durability of the connector, not the geosynthetic.

For additional information on the determination of the long-term creep reduced geosynthetic strength at the connection with the wall facing, see the long-term connection strength protocol as described in Appendix B of Berg et al. (2019) and Bathurst and Huang (2010). To determine $T_{crc}$, the connection creep testing and evaluation protocol in Berg et al. (2009), which consists of a series of connection creep tests carried out over an extended period of time to evaluate the potential for creep rupture at the connection, should be used. $CR_{cr}$ is taken as the creep-reduced connection strength, $T_{crc}$, extrapolated to the specified design life, divided by the ultimate wide-width

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$T_{lot}$ = ultimate wide-width tensile strength (ASTM D4595 or D6637) of the geosynthetic material used in the connection tests (lbs/ft)

If $CR_{cr}$ is determined based on long-term connection creep tests, $CR_{cr}$ shall be determined as follows:

$$CR_{cr} = \frac{T_{crc}}{T_{lot}} \qquad (11.10.6.4.4b\text{-}3)$$

where:

$T_{crc}$ = long-term creep reduced connection strength for the specified design life (lbs/ft)
$T_{lot}$ = ultimate wide-width tensile strength (ASTM D4595 or D6637) of the geosynthetic material used in the connection tests (lbs/ft)

Values for $RF_{CR}$ and $RF_D$ shall be determined as specified in Article 11.10.6.4.2b. The environment at the wall face connection may be different than the environment away from the wall face in the wall backfill. This shall be considered when determining $RF_{CR}$ and $RF_D$.

$CR_{cr}$ shall be determined at the anticipated vertical confining pressure at the wall face between the facing blocks. The vertical confining pressure shall be calculated using the Hinge Height Method as shown in Figure 11.10.6.4.4b-1 for a face batter, ω, of greater than 8 degrees. $T_{ac}$ should not be greater than $T_{at}$.

Geosynthetic walls may be designed using a flexible reinforcement sheet as the facing using only an overlap with the main soil reinforcement. The overlaps shall be designed using a pullout methodology. By replacing $T_{max}$ with $T_o$, Eq. 11.10.6.3.2-1 may be used to determine the minimum overlap length required, but in no case shall the overlap length be less than 3.0 ft. If tan ρ is determined experimentally based on soil to reinforcement contact, tan ρ shall be reduced by 30 percent where reinforcement-to-reinforcement contact is anticipated.

tensile strength (ASTM D4595 or D6637) for the reinforcement material lot used for the connection strength testing, $T_{lot}$.

If the connectors between blocks are intended to be used for maintaining block alignment during wall construction and are not intended for long-term connection shear capacity, the alignment connectors should be removed before assessing the connection capacity for the selected block–geosynthetic combination. If the pins or other connection devices are to be relied upon for long-term capacity, the durability of the connector material must be established.

Requirements for determining $RF_{CR}$ and $RF_D$ from product-specific data are provided in Article 11.10.6.4.3b and its commentary. The use of default reduction factors may be acceptable where the reinforcement load is maximum, i.e., in the middle of the wall backfill, and still not be acceptable at the facing connection if the facing environment is defined as aggressive.

All rights reserved. Duplication is a violation of applicable law.

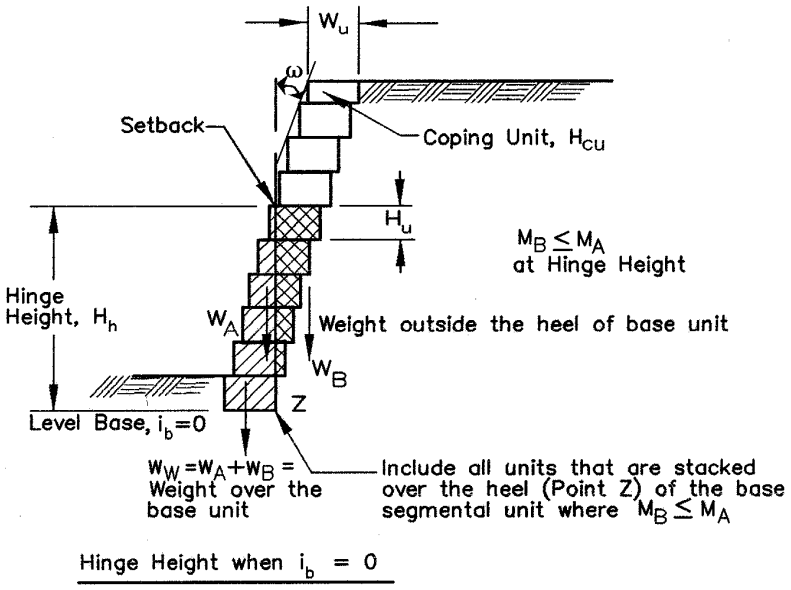

**Figure 11.10.6.4.4b-1—Determination of Hinge Height for Segmental Concrete Block Faced MSE Walls**

The hinge height, $H_h$, shown in Figure 11.10.6.4.4b-1, shall be determined as:

$$H_h = 2\left[\left(W_u - G_u - 0.5H_u \tan i_b\right)\cos i_b\right]\Big/\tan\left(\omega + i_b\right) \quad (11.10.6.4.4b\text{-}2)$$

where:

$H_u$ = segmental facing block unit height (ft)
$W_u$ = segmental facing block unit width, front to back (ft)
$G_u$ = distance to the center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft)
ω = wall batter due to setback per course (degrees)
$H$ = total height of wall (ft)
$H_h$ = hinge height (ft)

## 11.10.7—Seismic Design of MSE Walls

### 11.10.7.1—External Stability

External stability evaluation of MSE walls for seismic loading conditions shall be conducted as specified in Article 11.6.5, except as modified in this Article for MSE wall design.

Wall mass inertial forces, $P_{IR}$, shall be calculated based on an effective mass having a minimum width equal to the structural facing width, $W_u$, plus a portion of the reinforced backfill equal to 50 percent of the effective height of the wall. For walls in which the wall backfill

### C11.10.7.1

Since the reinforced soil mass is not really a rigid block, the inertial forces generated by seismic shaking are unlikely to peak at the same time in different portions of the reinforced mass when reinforcing strips or layers start becoming very long, as in the case of MSE walls with steep backslopes in moderately- to highly-seismic areas. This introduces excessive conservatism if the full length of the reinforcing strips is used in the inertia determination. Past design practice, as represented in

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

surface is horizontal, the effective height shall be taken equal to $H$ in Figure 11.10.7.1-1. For walls with sloping backfills, the inertial force, $P_{IR}$, shall be based on an effective mass having a height $H_2$ and a base width equal to a minimum of 0.5 $H_2$, in which $H_2$ is determined as follows:

$$H_2 = H + \frac{0.5H\tan(\beta)}{\left[1 - 0.5\tan(\beta)\right]} \qquad (11.10.7.1\text{-}1)$$

where:

$\beta$ = slope of backfill (degrees)

$P_{IR}$ for sloping backfills shall be determined as:

$$P_{IR} = P_{ir} + P_{is} \qquad (11.10.7.1\text{-}2)$$

where:

$P_{ir}$ = the inertial force caused by acceleration of the reinforced backfill (kips/ft)
$P_{is}$ = the inertial force caused by acceleration of the sloping soil surcharge above the reinforced backfill (kips/ft)

$P_{IR}$ shall act at the combined centroid of reinforced wall mass inertial force, $P_{ir,}$ and the inertial force resulting from the mass of the soil surcharge above the reinforced wall volume, $P_{is}$. $P_{ir}$ shall include the inertial force from the wall facing. The determination of the MSE wall inertial forces shall be as illustrated in Figure 11.10.7.1-1.

previous editions of these Specifications prior to the 6th, recommended that wall mass inertial force be limited to a soil volume equal to 50 percent of the effective height of the wall.

All rights reserved. Duplication is a violation of applicable law.

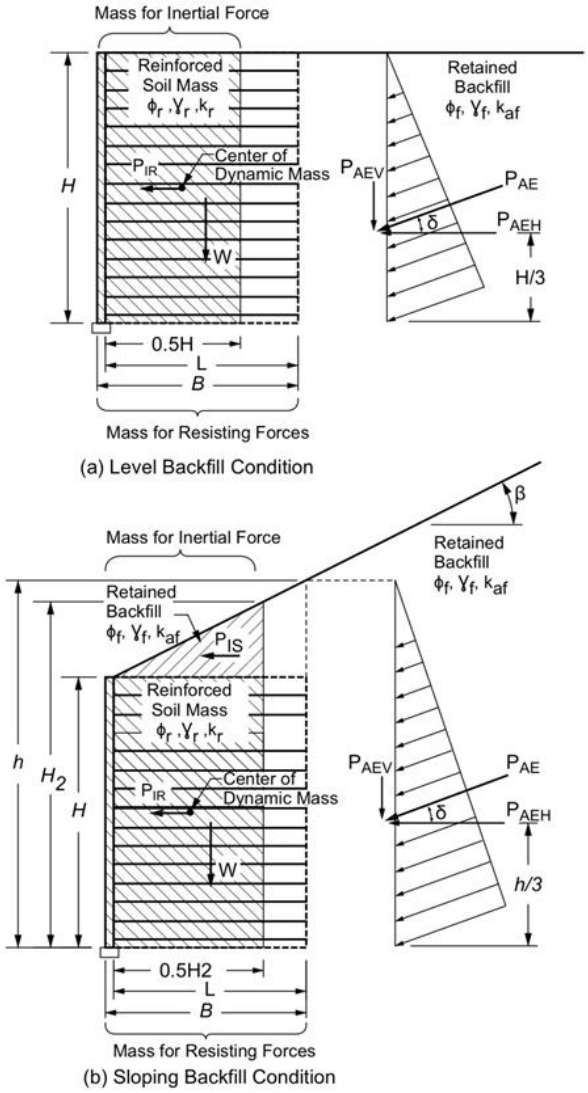

**Figure 11.10.7.1-1—Seismic External Stability of an MSE Wall**

### 11.10.7.2—Internal Stability

Reinforcements shall be designed to withstand horizontal forces generated by the internal inertia force, $P_i$, and the static forces. The total inertia force, $P_i$, per unit length of structure shall be considered equal to the mass of the active zone times the wall acceleration coefficient, $k_h$, reduced for lateral displacement of the wall during shaking. The reduced acceleration coefficient, $k_h$, should be consistent with the value of $k_h$ used for external stability.

For walls with inextensible (e.g., steel) reinforcement, this inertial force shall be distributed to the reinforcements proportionally to their resistant areas on a load per unit width of wall basis as follows:

$$T_{md} = P_i \frac{L_{ei}}{\sum_{i=1}^{m}(L_{ei})} \qquad (11.10.7.2\text{-}1)$$

### C11.10.7.2

In past design practice, as presented in previous editions of these Specifications prior to the 6th, the design method for seismic internal stability assumed that the internal inertial forces generating additional tensile loads in the reinforcement act on an active pressure zone that is assumed to be the same as that for the static loading case. A bilinear zone is defined for inextensible reinforcements such as metallic strips and a linear zone for extensible strips.

Whereas it could reasonably be anticipated that these active zones would extend outwards for seismic cases, as for M–O analyses, results from numerical and centrifuge models indicate that the reinforcement restricts such outward movements and only relatively small changes in location are seen.

In past design practice, as presented in previous editions of these Specifications prior to the 6th, the total inertial force was distributed to the reinforcements in

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For walls with extensible reinforcement, this inertial force shall be distributed uniformly to the reinforcements on a load per unit width of wall basis as follows:

$$T_{md} = \left( \frac{P_i}{n} \right) \qquad (11.10.7.2\text{-}2)$$

where:

$T_{md}$ = incremental dynamic inertia force at Layer $i$ (kips/ft)
$P_i$ = internal inertia force due to the weight of backfill within the active zone, i.e., the shaded area on Figure 11.10.7.2-1 (kips/ft)
$K_h W_a$ = where $W_a$ is the weight of the active zone and $K_h$ is calculated as specified in Article 11.6.5.1.
$n$ = total number of reinforcement layers in the wall (dim)
$L_{ei}$ = effective reinforcement length for layer $i$ (ft)

This pressure distribution should be determined from the total inertial force using $k_h$ (after reduction for wave scattering and lateral displacement).

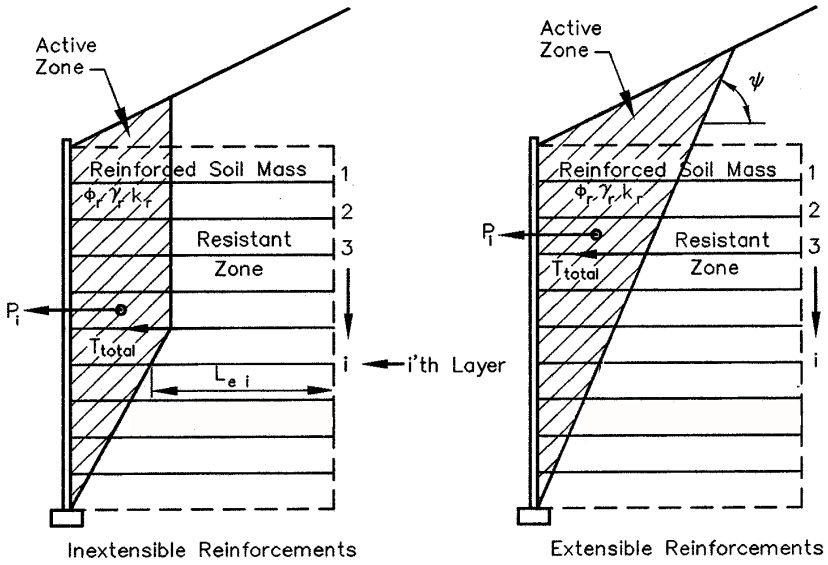
The total factored load applied to the reinforcement on a load per unit of wall width basis as shown in Figure 11.10.7.2-1 is determined as follows:

$$T_{totalf} = \gamma_{seis} \left( T_{max} + T_{md} \right) \qquad (11.10.7.2\text{-}3)$$

where:

$T_{max}$ = the static load applied to the reinforcements determined as specified in Article 11.10.6.2.1 (kips/ft)
$\gamma_{seis}$ = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load for Extreme Event I (dim)

The value for $\gamma_{seis}$ is as specified in Table 3.4.1-1 for *EQ* in Extreme Event I.



proportion to the effective resistant lengths, $L_{ei}$. This approach followed the finite element modeling conducted by Segrestin and Bastick (1988) and led to higher tensile forces in lower reinforcement layers.

In the case of internal stability evaluation, Vrymoed (1989) used a tributary area approach that assumes that the inertial load carried by each reinforcement layer increases linearly with height above the toe of the wall for equally spaced reinforcement layers. A similar approach was used by Ling et al. (1997) in limit equilibrium analyses as applied to extensible geosynthetic reinforced walls. This concept would suggest that longer reinforcement lengths could be needed at the top of walls with increasing acceleration levels, and the AASHTO approach could be unconservative, at least for geosynthetic reinforced walls. Numerical modeling of both steel and geosynthetic reinforced walls by Bathurst and Hatami (1999) shows that the distribution of the reinforcement load increase caused by seismic loading tends to become more uniform with depth as the reinforcement stiffness decreases, resulting in a uniform distribution for geosynthetic reinforced wall systems and a triangular distribution for typical steel reinforced wall systems. Hence, the Segrestin and Bastick (1988) method has been preserved for steel reinforced wall systems and, for geosynthetic reinforced wall systems, a uniform load distribution approach is specified.

With regard to the horizontal acceleration coefficient, $k_h$, past editions of these Specifications prior to the 6th have not allowed $k_h$ to be reduced to account for lateral deformation. Based on the excellent performance of MSE walls in earthquakes to date, it appears that this is likely a conservative assumption and it is therefore reasonable to allow reduction of $k_h$ for internal stability design corresponding to the lateral displacement permitted in the design of the wall for external stability.

The load factor for reinforcement load due to dead load, $T_{max}$, and the seismically induced load, $T_{md}$, is not given a specific designations in Table 3.4.1-1, but instead are set equal to 1.0 under the load designation *EQ*. The designation for this load factor of $\gamma_{seis}$ is provided in Eqs. 11.10.7.2-3 through 11.10.7.2-5 to demonstrate that $T_{totalf}$ is indeed a factored load.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$\psi$ = angle of active zone boundary as determined from Figure 11.10.6.3.1-1.
$P_i$ = internal inertial force due to weight of backfill within the active zone.
$L_{ei}$ = length of reinforcement in the resistant zone of the *i*th layer.
$T_{max}$ = load per unit wall width applied to each reinforcement layer due to static forces.
$T_{md}$ = load per unit wall width applied to each reinforcement layer due to dynamic forces.

**Figure 11.10.7.2-1—Seismic Internal Stability of an MSE Wall**

For geosynthetic reinforcement rupture, the reinforcement shall be designed to resist the static and dynamic components of the load determined as:

For the static component:

$$S_{rs} > \frac{\left(\gamma_{seis} T_{\max} RF\right)}{\left(\phi R_c\right)} \qquad (11.10.7.2\text{-}4)$$

For the dynamic component:

$$S_{rt} \geq \frac{\left(\gamma_{seis} T_{md} RF_{ID} RF_D\right)}{\left(\phi R_c\right)} \qquad (11.10.7.2\text{-}5)$$

where:

$\gamma_{seis}$ = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load (dim.)
$\phi$ = resistance factor for combined static/earthquake loading from Article 11.5.8 (dim.)
$S_{rs}$ = ultimate reinforcement tensile resistance required to resist static load component (kips/ft)

The reinforcement must be designed to resist the dynamic component of the load at any time during its design life. Design for static loads requires the strength of the reinforcement at the end of the design life to be reduced to account for creep and other degradation mechanisms. Strength loss in polymeric materials due to creep requires long term, sustained loading. The dynamic component of load for seismic design is a transient load (i.e., no long-term sustained loading for the dynamic component). Therefore, the creep reduction factor does not need to be considered for the dynamic component of the load. The resistance of the reinforcement to the static component of load, $T_{max}$, must, therefore, be handled separately from the dynamic component of load, $T_{md}$. The strength required to resist $T_{max}$ must include the effects of creep, but the strength required to resist $T_{md}$ should not include the effects of creep.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$S_{rt}$ = ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)
$R_c$ = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)
$RF$ = combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical aging specified in Article 11.10.6.4.3b (dim.)
$RF_{ID}$ = strength reduction factor to account for installation damage to reinforcement specified in Article 11.10.6.4.3b (dim.)
$RF_D$ = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation specified in Article 11.10.6.4.3b (dim.)

The required ultimate tensile resistance of the geosynthetic reinforcement shall be determined as:

$$T_{ult} = S_{rs} + S_{rt} \tag{11.10.7.2-6}$$

For pullout of steel or geosynthetic reinforcement:

$$L_e \geq \frac{T_{totalf}}{\left(\phi\left(0.8F^* \alpha \sigma_v C R_c\right)\right)} \tag{11.10.7.2-7}$$

where:

$L_e$ = length of reinforcement in resisting zone (ft)
$T_{total}$ = maximum factored reinforcement tension from Eq. 11.10.7.2-2 (kips/ft)
$\phi$ = resistance factor for reinforcement pullout from Table 11.5.7-1 (dim.)
$F^*$ = pullout friction factor (dim.)
$\alpha$ = scale effect correction factor (dim.)
$\sigma_v$ = unfactored vertical stress at the reinforcement level in the resistant zone (ksf)
$C$ = overall reinforcement surface area geometry factor (dim.)
$R_c$ = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)

For seismic loading conditions, the value of $F^*$, the pullout resistance factor, is reduced to 80 percent of the value used for static design, unless dynamic pullout tests are performed to directly determine the $F^*$ value. Hence, the coefficient of 0.8 is included in Eq. 11.10.7.2-7.

### 11.10.7.3—Facing Reinforcement Connections

C11.10.7.3

Facing elements shall be designed to resist the seismic loads determined as specified in Article 11.10.7.2, i.e., $T_{total}$. Facing elements shall be designed in accordance with applicable provisions of Sections 5, 6, and 8 for reinforced concrete, steel, and timber, respectively, except that for the Extreme Event I limit state, all resistance factors should be 1.0, unless otherwise specified for this limit state.

For segmental concrete block faced walls, the blocks located above the uppermost backfill reinforcement layer shall be designed to resist toppling failure during seismic loading.

For geosynthetic connections subjected to seismic loading, the factored long-term connection strength, $\phi T_{ac}$, must be greater than the factored reinforcement load, $T_{totalf}$. If the connection strength is partially or fully dependent on friction between the facing blocks and the reinforcement, the connection strength to resist seismic loads shall be reduced to 80 percent of its static value as follows:

For the static component of the load:

$$S_{rs} \geq \frac{\gamma_{seis} T_{max} RF_D}{0.8 \phi CR_{cr} R_c} \tag{11.10.7.3-1}$$

For the dynamic component of the load:

$$S_{rt} \geq \frac{\gamma_{seis} T_{md} RF_D}{0.8 \phi CR_u R_c} \tag{11.10.7.3-2}$$

where:

$\gamma_{seis}$ = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load (dim)
$S_{rs}$ = ultimate reinforcement tensile resistance required to resist static load component (kip/ft)
$T_{max}$ = applied load to reinforcement (kip/ft)
$RF_D$ = reduction factor to prevent rupture of reinforcement due to chemical and biological degradation specified in Article 11.10.6.4.4b (dim.)
$\phi$ = resistance factor from Table 11.5.7-1 (dim.)
$CR_{cr}$ = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)
$R_c$ = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)
$S_{rt}$ = ultimate reinforcement tensile resistance required to resist dynamic load component (kip/ft)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$T_{md}$ = factored incremental dynamic inertia force (kip/ft)
$CR_u$ = short-term reduction factor to account for reduced ultimate strength resulting from connection as specified in Article C11.10.6.4.4b (dim.)

For structural connections that do not rely on a frictional component, the 0.8 multiplier may be removed from Eqs. 11.10.7.3-1 and 11.10.7.3-2.

The required ultimate tensile resistance of the geosynthetic reinforcement at the connection is:

$$T_{ult} = S_{rs} + S_{rt} \quad (11.10.7.3\text{-}3)$$

For structures in seismic performance Zones 3 or 4, facing connections in segmental block faced walls shall use shear resisting devices between the facing blocks and soil reinforcement, such as shear keys, pins, etc., and shall not be fully dependent on frictional resistance between the soil reinforcement and facing blocks.

The connection capacity of a facing/reinforcement connection system that is fully dependent on the shear resisting devices for the connection capacity will not be significantly influenced by the normal stress between facing blocks. The percentage of connection load carried by the shear resisting devices relative to the frictional resistance to meet the specification requirements should be determined based on past successful performance of the connection system.

Some judgment may be required to determine whether or not a specific shear resisting device or combination of devices is sufficient to meet this requirement in Seismic Performance Zones 3 and 4. The ability of the shear resisting device or devices to keep the soil reinforcement connected to the facing, should vertical acceleration significantly reduce the normal force between the reinforcement and the facing blocks, should be evaluated. Note that in some cases, coarse angular gravel placed within the hollow core of the facing blocks, provided that the gravel can remain interlocked during shaking, can function as a shear restraining device to meet the requirements of this Article.

### 11.10.7.4—Wall Details for Improved Seismic Performance

The details specified in Article 11.6.5.6 for gravity walls should also be addressed for MSE walls in seismically active areas, defined as Seismic Zone 2 or higher. The following additional requirements should also be addressed for MSE walls:

- *Second Stage Fascia Panels*: The connections used to connect the fascia panels to the main gravity wall structure should be designed to minimize movement between panels during shaking.
- *Soil Reinforcement Length*: A minimum soil reinforcement length of 0.7*H* should be used. A greater soil reinforcement length in the upper 2.0 to 4.0 ft of wall height (a minimum of two reinforcement layers) should also be considered to improve the seismic performance of the wall.

### C11.10.7.4

These recommended details are based on previous experiences with walls in earthquakes (e.g., see Yen et al., 2011). Walls that did not address these details tended to have a higher frequency of problems than walls that did consider these details.

With regard to preventing joints from opening up during shaking, such as at corners and protrusions through the wall face, Article C11.6.5.6 applies. For panel-faced MSE walls placed against a cast-in-place (CIP) concrete curtain wall or similar structure, a 4.0-in. lip on the CIP structure to cover the joint with the MSE wall facing has been used successfully.

Historically, corners and abrupt alignment changes in walls (e.g., corners and short-radius turns at an enclosed angle of 120 degrees or less) have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

If the wall is placed immediately in front of a very steep slope, existing shoring, or permanent wall, the reinforcement within the upper 2.0 to 4.0 ft of wall height (a minimum of two reinforcement layers, applicable to wall heights of 10.0 ft or more) should be extended to at least 5.0 ft behind the steep slope or existing wall.

should be considered when designing and detailing a wall corner for seismic loading. Reinforcement layers should be placed in both directions at the corner, abrupt alignment change, or short-radius turn. In addition, the special corner facing element, used to bridge across a continuous vertical corner joint, should also have a reinforcement layers attached to it to provide stability for the corner panel element. For modular block faced walls in which the blocks are staggered such that a continuous vertical joint is not formed, placing soil reinforcement as continuous or staggered layers across the corner is an acceptable approach to provide an adequate degree of continuity and stability across the corner. For concrete panel faced systems, that portion of the corner or abrupt wall facing alignment change where the soil reinforcement cannot achieve its full length required to meet internal stability requirements, the end of the reinforcement layer should be structurally tied to the back of the adjacent panel. The reinforcement layers that are tied to both sides of the corner should be designed considering the corner as a bin structure. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

Note that the corner or abrupt alignment change enclosed angle as defined in the previous paragraph can either be internal or external to the wall.

With regard to wall backfill materials, the provisions of Article 11.6.5.6 shall apply.

When structures and foundations within the active zone of the reinforced wall backfill are present, significant wall movements and damage have occurred during earthquakes due to inadequate reinforcement length behind the facing due to the presence of a foundation, drainage structure, or other similar structure. The details provided in Article 11.10.10.4 are especially important to implement for walls subjected to seismic loading.

Past experience with second stage precast incremental facing panels indicates that performance problems can occur if the connections between the panels and the first stage wall can rotate or otherwise have some looseness, especially if wall settlement is not complete. Therefore, incremental second stage facia panels should be avoided for walls located in seismically active areas (as defined in Article 11.5.4.2 for sites requiring seismic analysis). Full height second stage precast or CIP concrete panels have performed more consistently, provided the panels are installed after wall settlement is essentially complete.

A minimum soil reinforcement length of 0.7$H$ has been shown to consistently provide good performance of MSE walls in earthquakes. Extending the upper two layers of soil reinforcement a few feet behind the 0.7$H$ reinforcement length has, in general, resulted in modest improvement in the wall deformation in response to seismic loading, especially if higher silt content backfill

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

must be used. If MSE walls are placed in front of structures or hard soil or rock steep slopes that could have different deformation characteristics than the MSE wall reinforced backfill, there is a tendency for a crack to develop at the vertical or near-vertical boundary of the two materials. Soil reinforcements that extend an adequate distance behind the boundary have been shown to prevent such a crack from developing. It is especially important to extend the length of the upper reinforcement layers if there is inadequate room to have a reinforcement length of 0.7*H* in the bottom portion of the wall, provided the requirements of Article 11.10.2.1 and commentary are met.

For additional information on good wall details for MSE walls, see Berg et al. (2009).

### 11.10.8—Drainage

Internal drainage measures shall be provided for all structures to prevent saturation of the reinforced backfill and to intercept any surface flows containing aggressive elements.

MSE walls in cut areas and side-hill fills with established groundwater levels shall be constructed with drainage blankets in back of, and beneath, the reinforced zone.

For MSE walls supporting roadways which are chemically deiced in the winter, an impervious membrane may be required below the pavement and just above the first layer of soil reinforcement to intercept any flows containing deicing chemicals. The membrane shall be sloped to drain away from the facing to an intercepting longitudinal drain outletted beyond the reinforced zone. Typically, a roughened surface PVC, HDPE, or linear low-density polyethelyene (LLDPE) geomembrane with a minimum thickness of 30 mils. should be used. All seams in the membrane shall be welded to prevent leakage.

**C11.10.8**

MSE wall backfill meeting the requirements of Article 7.3.6.3 in the *AASHTO LRFD Bridge Construction Specifications* may not be adequately free draining to prevent build-up of water in the backfill, resulting in unanticipated loading of the reinforcement and facing. The ability of the backfill to drain quickly should be considered when deciding the type of drainage needed. However, in general, water from stormwater runoff as well as ground water that could seep into the backfill should be prevented from entering the MSE wall backfill and from building up immediately behind the MSE wall.

### 11.10.9—Subsurface Erosion

The provisions of Article 11.6.3.5 shall apply.

### 11.10.10—Special Loading Conditions

#### 11.10.10.1—Concentrated Dead Loads

**C11.10.10.1**

The distribution of stresses within and behind the wall resulting from concentrated loads applied to the wall top or behind the wall shall be determined in accordance with Article 3.11.6.3.

Figure 11.10.10.1-1 illustrates the combination of loads using superposition principles to evaluate external and internal wall stability. Depending on the size and location of the concentrated dead load, the location of the boundary between the active and resistant zones may have to be adjusted as shown in Figure 11.10.10.1-2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For distribution of loads within the reinforced soil zone of the wall, the factored horizontal force carried by the reinforcement at any reinforcement level, $T_{totalf}$, shall be determined by superposition as follows:

$$T_{totalf} = \gamma_{p-EV} T_{\max} + \gamma_{p-ES} S_v \left( k_r \Delta\sigma_v + \Delta\sigma_H \right) \quad (11.10.10.1\text{-}1)$$

where:

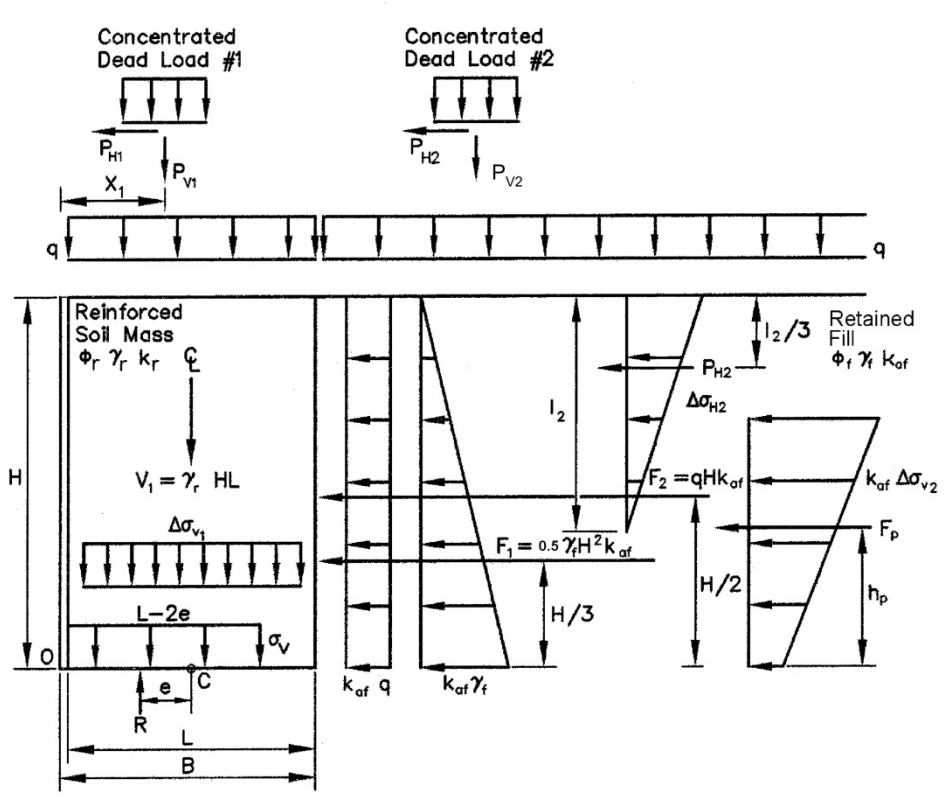
$\gamma_{p\text{-}EV}$ = load factor for vertical earth pressure specified in Table 3.4.1-2 (dim.)
$\gamma_{p\text{-}ES}$ = load factor for earth surcharge, *ES*, in Table 3.4.1-2
$\Delta\sigma_v$ = vertical soil stress due to concentrated load such as a footing load (ksf)
$\Delta\sigma_H$ = horizontal stress at reinforcement level resulting from a concentrated horizontal surcharge load (ksf)
$S_v$ = tributary layer vertical thickness for reinforcement (ft)
$k_r$ = lateral earth pressure coefficient (dim.)

At the connection with the wall facing, Eq. 11.10.10.1-2 shall be modified to be as follows:

$$T_{totalfo} = \gamma_{p-EV} T_o + \gamma_{p-ES} S_v \left( k_r \Delta\sigma_v + \Delta\sigma_H \right) \quad (11.10.10.1\text{-}2)$$

where:

$T_{totalfo}$ = the factored reinforcement load at the connection to the facing (kips/ft)
$T_o$ = nominal (unfactored) tensile load at reinforcement/facing connection (kips/ft)



All other variables are as defined previously.

For the Coherent Gravity Method, $k_r$ shall be determined from Figure 11.10.6.2.1d-1. Additionally for the Coherent Gravity Method, the contribution of the concentrated dead loads to the load eccentricity at each reinforcement layer shall be estimated using the principles illustrated in Figure 11.10.6.2.1d-2. Any external concentrated loads present which contribute to $T_{max}$ shall be factored as specified in Tables 3.4.1-1 and 3.4.1-2.

For the Stiffness Method, $k_r$ in Eq. 11.10.10.1-1 shall be equal to $k_{avh}$ for walls with a facing batter of 10 degrees or less from the vertical, determined as specified in Article 11.10.6.2.1e. Any external concentrated loads added by superposition which contribute to $T_{max}$ shall be factored as specified in Tables 3.4.1-1 and 3.4.1-2.

For walls with a facing batter of greater than 10 degrees, see Article C11.10.6.2.1c to determine the lateral earth pressure coefficient.

All rights reserved. Duplication is a violation of applicable law.

Notes:

These equations assume that concentrated dead load #2 is located within the active zone behind the reinforced soil mass.

For relatively thick facing elements (e.g., segmental concrete facing blocks), it is acceptable to include the facing dimensions and weight in sliding, overturning, and bearing capacity calculations (i.e., use $B$ in lieu of $L$).

$P_{V1}$, $P_{H1}$, $\Delta\sigma_{v1}$, $\Delta\sigma_{v2}$, $\Delta\sigma_{H2}$, and $I_2$ are as determined from Figures 3.11.6.3-1 and 3.11.6.3-2, and $F_p$ results from $P_{V2}$ (i.e., $K\Delta\sigma_{v2}$ from Figure 3.11.6.3-1. $H$ is the total wall height at the face. $h_p$ is the distance between the centroid of the trapezoidal distribution shown and the bottom of that distribution.

**Figure 11.10.10.1-1—Superposition of Concentrated Dead Loads for External and Internal Stability Evaluation**

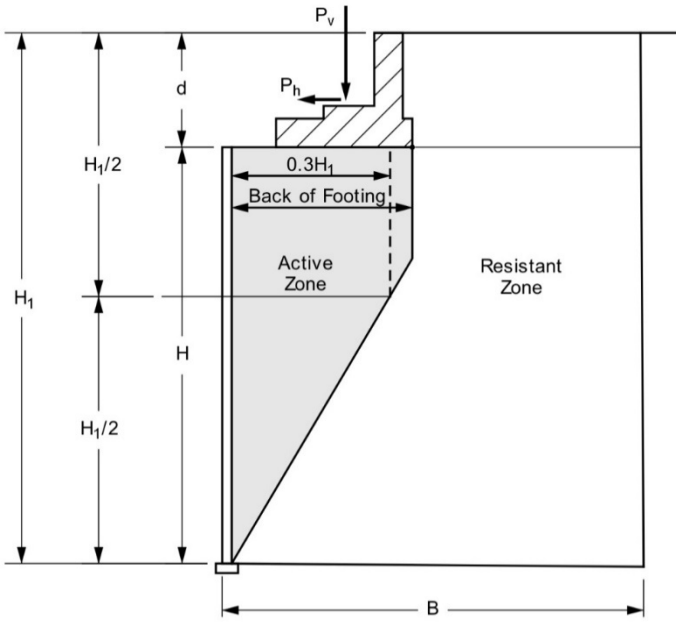

**Figure 11.10.10.1-2—Location of Maximum Tensile Force Line in Case of Large Surcharge Slabs (Inextensible Reinforcements)**

### 11.10.10.2—Traffic Loads and Barriers

Traffic loads shall be treated as uniform surcharge loads in accordance with the criteria outlined in Article 3.11.6.2. The live load surcharge pressure shall not be less than 2.0 ft of earth. Parapets and traffic barriers, constructed over or in line with the front face of the wall, shall be designed to resist overturning moments by their own mass. Base slabs shall not have any transverse joints, except construction joints, and adjacent slabs shall be joined by shear dowels. The upper layer(s) of soil reinforcements shall have sufficient tensile capacity to resist a concentrated horizontal load of $\gamma_{LL}P_H$ where $P_H$ = 10 kips distributed over a barrier length of 5.0 ft. This force distribution accounts for the local peak force in the soil reinforcements in the vicinity of the concentrated load. This distributed force would be equal to $\gamma_{LL}P_{H1}$ where $P_{H1}$ = 2.0 kips/ft and is applied as shown in Figure 3.11.6.3-2a. $\gamma_{LL}P_{H1}$ would be distributed to the reinforcements assuming $b_f$ equal to the width of the base slab. Adequate space shall be provided laterally between the back of the facing panels and the traffic barrier/slab to allow the traffic barrier and slab to resist the impact load in sliding and overturning without directly transmitting load to the top facing units.

For checking pullout safety of the reinforcements, the lateral traffic impact load shall be distributed to the upper soil reinforcement using Figure 3.11.6.3-2a, assuming $b_f$ equal to the width of the base slab. The full length of reinforcements shall be considered effective in resisting pullout due to the impact load. The upper layer(s) of soil reinforcement shall have sufficient pullout capacity to resist a horizontal load of $\gamma_{LL}P_{H1}$ where $P_{H1}$ = 10.0 kips distributed over a 20.0 ft base slab length.

### C11.10.10.2

The force distribution for pullout calculations is different than that used for tensile calculations because the entire base slab must move laterally to initiate a pullout failure due to the relatively large deformation required.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Due to the transient nature of traffic barrier impact loads, when designing for reinforcement rupture, the geosynthetic reinforcement must be designed to resist the static and transient (impact) components of the load as follows:

For the static component, see Eq. 11.10.7.2-4.

For the transient components:

$$\gamma_{CT}\Delta\sigma_H S_v \le \frac{\phi S_{rt} R_c}{RF_{ID} RF_D} \qquad (11.10.10.2\text{-}1)$$

where:

$\gamma_{CT}$ = load factor for vehicular impact loads (dim.)
$\Delta\sigma_H$ = traffic barrier impact stress applied over reinforcement tributary area per Article 11.10.10.1 (ksf)
$S_v$ = vertical spacing of reinforcement (ft)
$S_{rt}$ = ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)
$R_c$ = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)
$RF_{ID}$ = strength reduction factor to account for installation damage to reinforcement from Article 11.10.6.4.3b (dim.)
$RF_D$ = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation from Article 11.10.6.4.3b (dim.)

The reinforcement strength required for the static load component must be added to the reinforcement strength required for the transient load component to determine the required total ultimate strength using Eq. 11.10.7.3-3.

Parapets and traffic barriers shall satisfy crash testing requirements as specified in Section 13. The anchoring slab shall be strong enough to resist the ultimate strength of the standard parapet.

Flexible post and beam barriers, when used, shall be placed at a minimum distance of 3.0 ft from the wall face, driven 5.0 ft below grade, and spaced to miss the reinforcements where possible. If the reinforcements cannot be missed, the wall shall be designed accounting for the presence of an obstruction as described in Article 11.10.10.4. The upper two rows of reinforcement shall be designed for an additional horizontal load $\gamma P_{H1}$, where $P_{H1}$ = 300 lb per linear ft of wall, 50 percent of which is distributed to each layer of reinforcement.

**11.10.10.3—Hydrostatic Pressures**

For structures along rivers and streams, a minimum differential hydrostatic pressure equal to 3.0 ft of water shall be considered for design. This load shall be applied

Refer to C11.10.7.2 which applies to transient loads, such as impact loads on traffic barriers, as well as earthquake loads.

**C11.10.10.3**

Situations where the wall is influenced by tide or river fluctuations may require that the wall be designed for rapid drawdown conditions, which could result in

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

at the high-water level. Effective unit weights shall be used in the calculations for internal and external stability beginning at levels just below the application of the differential hydrostatic pressure.

differential hydrostatic pressure considerably greater than 3.0 ft, or alternatively rapidly draining backfill material such as shot rock or open graded coarse gravel can be used as backfill. Backfill material meeting the gradation requirements in the *AASHTO LRFD Bridge Construction Specifications* for MSE structure backfill is not considered to be rapid draining.

The phreatic surface for drawdown calculations will depend on the permeability of the MSE backfill. Using open-graded "free draining" backfill is preferred for good performance, however its use does not preclude the need to do a drawdown analysis.

### 11.10.10.4—Obstructions in the Reinforced Soil Zone

**C11.10.10.4**

If the placement of an obstruction in the wall soil reinforcement zone such as a catch basin, grate inlet, signal or sign foundation, guardrail post, or culvert cannot be avoided, the design of the wall near the obstruction shall be modified using one of the following alternatives:

1) Assuming reinforcement layers must be partially or fully severed in the location of the obstruction, design the surrounding reinforcement layers to carry the additional load which would have been carried by the severed reinforcements.
2) Place a structural frame around the obstruction capable of carrying the load from the reinforcements in front of the obstruction to reinforcements connected to the structural frame behind the obstruction as illustrated in Figure 11.10.10.4-1.
3) If the soil reinforcements consist of discrete strips and depending on the size and location of the obstruction, it may be possible to splay the reinforcements around the obstruction.

Field cutting of longitudinal or transverse wires of metal grids, e.g., bar mats, should not be allowed unless one of the alternatives in Article 11.10.10.4 is followed and compensating adjustment is made in the wall design.

Typically, the splay of reinforcements is limited to a maximum of 15 degrees.

For Alternative 1, the portion of the wall facing in front of the obstruction shall be made stable against a toppling (overturning) or sliding failure. If this cannot be accomplished, the soil reinforcements between the obstruction and the wall face can be structurally connected to the obstruction such that the wall face does not topple, or the facing elements can be structurally connected to adjacent facing elements to prevent this type of failure.

For the second alternative, the frame and connections shall be designed in accordance with Section 6 for steel frames.

Note that it may be feasible to connect the soil reinforcement directly to the obstruction, depending on the reinforcement type and the nature of the obstruction.

For the third alternative, the splay angle, measured from a line perpendicular to the wall face, shall be small enough that the splaying does not generate moment in the reinforcement or the connection of the reinforcement to the wall face. The tensile resistance of the splayed reinforcement shall be reduced by the cosine of the splay angle.

If the obstruction must penetrate through the face of the wall, the wall facing elements shall be designed to fit around the obstruction such that the facing elements are

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

stable, i.e., point loads should be avoided, and such that wall backfill soil cannot spill through the wall face where it joins the obstruction. To this end, a collar next to the wall face around the obstruction may be needed.

If driven piles or drilled shafts must be placed through the reinforced zone, the recommendations provided in Article 11.10.11 shall be followed.

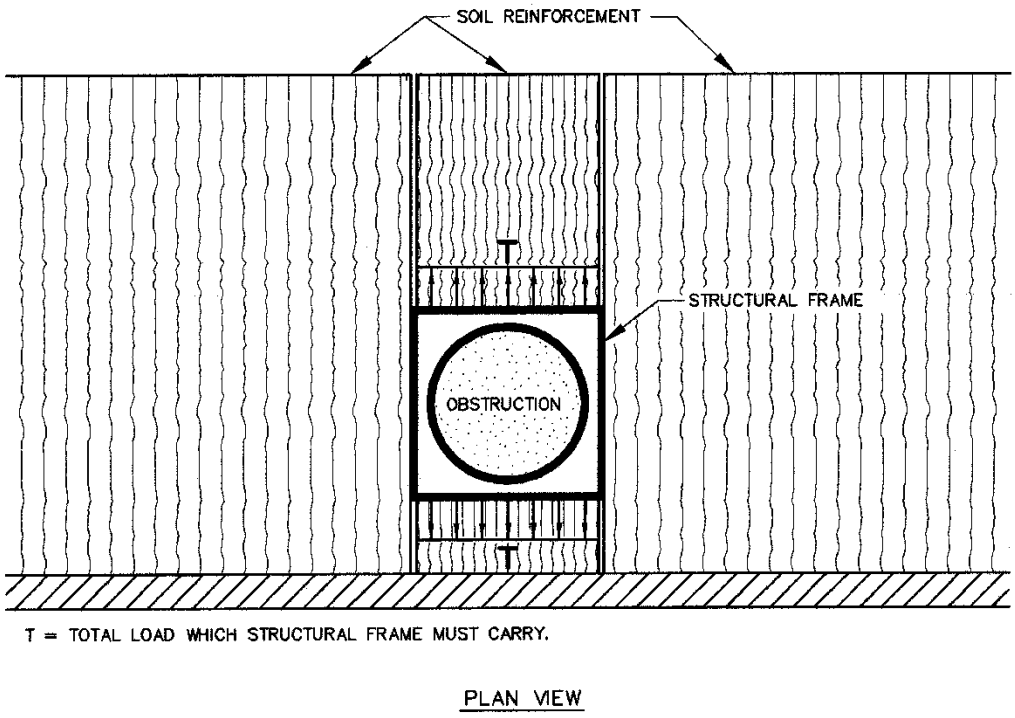

**Figure 11.10.10.4-1—Structural Connection of Soil Reinforcement around Backfill Obstructions**

### 11.10.11—MSE Abutments

Abutments with a bridge footing placed on top of the reinforced soil zone of an MSE wall shall be proportioned to meet the criteria specified in Articles 11.6.2 through 11.6.6.

The reinforced soil zone below the abutment footing shall be designed for the additional loads imposed by the footing pressure and supplemental earth pressures resulting from horizontal loads applied at the bridge seat and from the backwall. The footing load may be distributed as described in Article 11.10.10.1.

The factored horizontal force carried by the reinforcement at any reinforcement level, $T_{totalf}$, shall be determined by superposition using Eq. 11.10.10.1-1.

The effective length used for calculations of internal stability under the abutment footing shall be as described in Article 11.10.10.1 and Figure 11.10.10.1-2.

The minimum distance from the centerline of the bearing on the abutment to the outer edge of the facing shall be 3.5 ft. The minimum distance between the back face of the panel and the footing shall be 6.0 in.

### C11.10.11

The term "MSE abutment" is defined to represent the case when the bridge footing is placed directly above the reinforced soil zone of an MSE wall.

For analysis of the spread footing on top of the reinforced soil zone, the following values of bearing resistance of the reinforced soil zone may be used (Berg et al., 2009):

- For service limit state, bearing resistance = 4 ksf to limit the vertical movement to less than approximately 0.5 in. within the reinforced soil mass; and
- For strength limit state, factored bearing resistance = 7 ksf.

The minimum length of reinforcement, based on experience, has been $0.6(H + d) + 6.5$ ft. The length of reinforcement should be constant throughout the height to limit differential settlements across the reinforced zone. Differential settlements could overstress the reinforcements.

The permissible level of differential settlement at abutment structures should preclude damage to

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Where significant frost penetration is anticipated, the abutment footing shall be placed on a bed of compacted coarse aggregate 3.0 ft thick as described in Article 11.10.2.2.

The density, length, and cross-section of the soil reinforcements designed for support of the abutment shall be carried on the wingwalls for a minimum horizontal distance equal to 50 percent of the height of the abutment.

In pile or drilled shaft supported abutments, the horizontal forces transmitted to the deep foundation elements shall be resisted by the lateral capacity of the deep foundation elements by provision of additional reinforcements to tie the drilled shaft or pile cap into the soil mass, or by batter piles. Lateral loads transmitted from the deep foundation elements to the reinforced backfill may be determined using a *p-y* lateral load analysis technique. The facing shall be isolated from horizontal loads associated with lateral pile or drilled shaft deflections. A minimum clear distance of 1.5 ft shall be provided between the facing and deep foundation elements. Piles or drilled shafts shall be specified to be placed prior to wall construction and cased through the fill if necessary.

The equilibrium of the system should be checked at each level of reinforcement below the bridge seat.

Due to the relatively high bearing pressures near the panel connections, the adequacy and ultimate capacity of panel connections should be determined by conducting pullout and flexural tests on full-sized panels.

superstructure units. This subject is discussed in Article 10.6.2.2. In general, abutments should not be constructed on mechanically stabilized embankments if anticipated differential settlements between abutments or between piers and abutments are greater than one-half the limiting differential settlements described in Article C10.5.2.2.

Moments should be taken at each level under consideration about the centerline of the reinforced mass to determine the eccentricity of load at each level. A uniform vertical stress is then calculated using a fictitious width taken as $(B - 2e)$, and the corresponding horizontal stress should be computed by multiplying by the appropriate coefficient of lateral earth pressure.

## 11.11—PREFABRICATED MODULAR WALLS

### 11.11.1—General

Prefabricated modular systems may be considered where conventional gravity, cantilever, or counterfort concrete retaining walls are considered.

### C11.11.1

Prefabricated modular wall systems, whose elements may be proprietary, generally employ interlocking soil-filled reinforced concrete or steel modules or bins, rock-filled gabion baskets, precast concrete units, or dry cast segmental masonry concrete units (without soil reinforcement) which resist earth pressures by acting as gravity retaining walls. Prefabricated modular walls may also use their structural elements to mobilize the dead weight of a portion of the wall backfill through soil arching to provide resistance to lateral loads. Typical prefabricated modular walls are shown in Figure C11.11.1-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

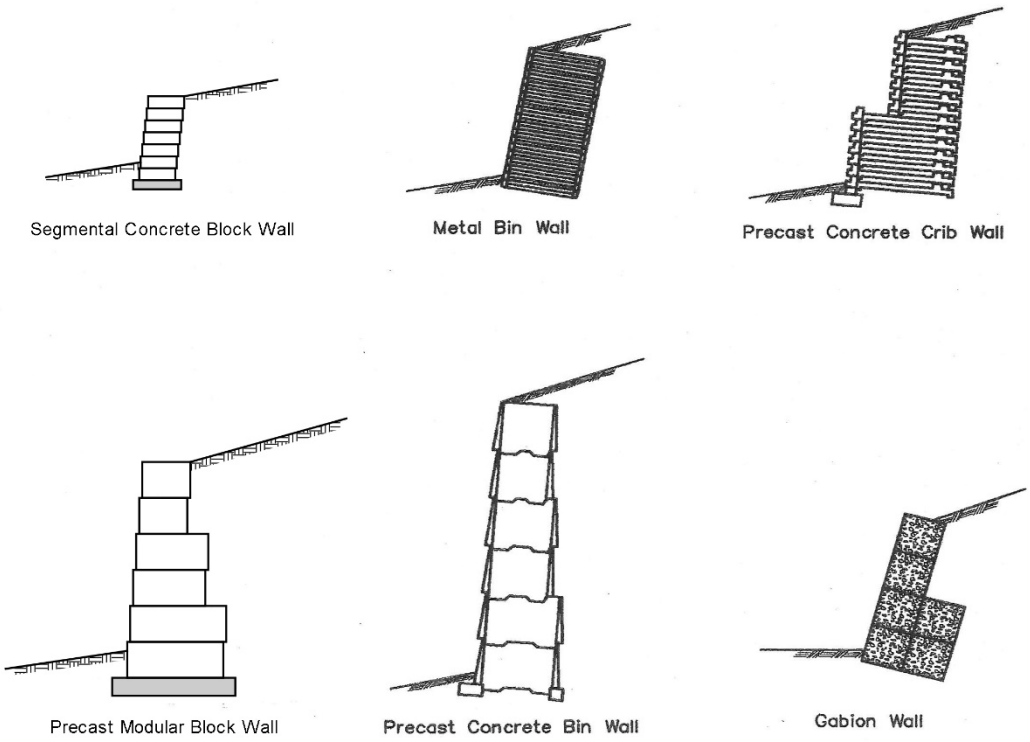

**Figure C11.11.1-1—Typical Prefabricated Modular Gravity Walls**

Prefabricated modular wall systems shall not be used under the following conditions:

- On curves with a radius of less than 800 ft, unless the curve can be substituted by a series of chords.
- Steel modular systems shall not be used where the groundwater or surface runoff is acid contaminated or where deicing spray is anticipated.

### 11.11.2—Loading

The provisions of Articles 11.6.1.2 and 3.11.5.9 shall apply, except that shrinkage and temperature effects need not be considered.

### 11.11.3—Movement at the Service Limit State

The provisions of Article 11.6.2 shall apply as applicable.

### C11.11.3

Calculated longitudinal differential settlements along the face of the wall should result in a slope less than $^{1}/_{200}$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

## 11.11.4—Safety against Soil Failure

### 11.11.4.1—General

For sliding and overturning stability, the system shall be assumed to act as a rigid body. Determination of stability shall be made at every module level.

Passive pressures shall be neglected in stability computations, unless the base of the wall extends below the depth of maximum scour, freeze–thaw, or other disturbance. For these cases only, the embedment below the greater of these depths may be considered effective in providing passive resistance.

### 11.11.4.2—Sliding

The provisions of Article 10.6.3.4 shall apply.

Computations for sliding stability may consider that the friction between the soil-fill and the foundation soil, and the friction between the bottom modules or footing and the foundation soil are effective in resisting sliding. The coefficient of sliding friction between the soil-fill and foundation soil at the wall base shall be the lesser of $\phi_f$ of the soil fill and $\phi_f$ of the foundation soil. The coefficient of sliding friction between the bottom modules or footing and the foundation soil at the wall base shall be reduced, as necessary, to account for any smooth contact areas.

In the absence of specific data, a maximum friction angle of 30 degrees shall be used for $\phi_f$ for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

### 11.11.4.3—Bearing Resistance

The provisions of Article 10.6.3 shall apply.

Bearing resistance shall be computed by assuming that dead loads and earth pressure loads are resisted by point supports per unit length at the rear and front of the modules or at the location of the bottom legs. A minimum of 80 percent of the soil weight inside the modules shall be considered to be transferred to the front and rear support points. If foundation conditions require a footing under the total area of the module, all of the soil weight inside the modules shall be considered.

**C11.11.4.3**

Concrete modular systems are relatively rigid and are subject to structural damage due to differential settlements, especially in the longitudinal direction. Therefore, bearing resistance for footing design should be determined as specified in Article 10.6.

### 11.11.4.4—Overturning

The provisions of Article 11.6.3.3 shall apply.

A maximum of 80 percent of the soil-fill inside the modules is effective in resisting overturning moments.

**C11.11.4.4**

The entire volume of soil within the module cannot be counted on to resist overturning, as some soil will not arch within the module. If a structural bottom is provided to retain the soil within the module, no reduction of the soil weight to compute overturning resistance is warranted.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 11.11.4.5—Subsurface Erosion

Bin walls may be used in scour-sensitive areas only where their suitability has been established. The provisions of Article 11.6.3.5 shall apply.

#### 11.11.4.6—Overall Stability

The provisions of Article 3.4.1 and Article 11.6.3.7 shall apply.

#### 11.11.4.7—Passive Resistance and Sliding

The provisions of Articles 10.6.3.4 and 11.6.3.6 shall apply, as applicable.

### 11.11.5—Safety against Structural Failure

#### 11.11.5.1—Module Members

Prefabricated modular units shall be designed for the factored earth pressures behind the wall and for factored pressures developed inside the modules. Rear face surfaces shall be designed for both the factored earth pressures developed inside the modules during construction and the difference between the factored earth pressures behind and inside the modules after construction. Strength and reinforcement requirements for concrete modules shall be in accordance with Section 5.

Strength requirements for steel modules shall be in accordance with Section 6. The net section used for design shall be reduced in accordance with Article 11.10.6.4.2a.

Factored bin pressures shall be the same for each module and shall not be less than:

$$P_b = \gamma \gamma_s b \qquad (11.11.5.1\text{-}1)$$

where:

$P_b$ = factored pressure inside bin module (ksf)
$\gamma_s$ = soil unit weight (kcf)
$\gamma$ = load factor for vertical earth pressure specified in Table 3.4.1-2
$b$ = width of bin module (ft)

Steel reinforcing shall be symmetrical on both faces unless positive identification of each face can be ensured to preclude reversal of units. Corners shall be adequately reinforced.

#### C11.11.5.1

Structural design of module members is based on the difference between pressures developed inside the modules (bin pressures) and those resulting from the thrust of the backfill. The recommended bin pressure relationships are based on relationships obtained for long trench geometry, and are generally conservative.

All rights reserved. Duplication is a violation of applicable law.

### 11.11.6—Seismic Design for Prefabricated Modular Walls

The provisions of Article 11.6.5 shall apply.

### C11.11.6

The prefabricated modular wall develops resistance to seismic loads from both the geometry and the weight of the wall section. The primary design issues for seismic loading are global stability, external stability (i.e., sliding, overturning, and bearing), and internal stability. External stability includes the ability of each lift within the wall to also meet external stability requirements. Interlocking between individual structural sections and the soil fill within the wall needs to be considered in this evaluation.

The primary difference for this wall type relative to a gravity or semigravity wall is that sliding and overturning can occur at various heights between the base and top of the wall, as this class of walls typically uses gravity to join sections of the wall together.

The interior of the prefabricated wall elements is normally filled with soil; this provides both additional weight and shear between structural elements. The contributions of the earth, as well as the batter on the wall, need to be considered in the analysis.

Similar to the other external stability checks, the overall (global) stability check needs to consider failure surfaces that pass through the wall section, as well as below the base of the wall. The check on stability at mid-level must consider the contributions of both the soil within the wall and any structural interlocking that occurs for the particular modular wall type.

When checking stability at the mid-level of a wall, the additional shear resistance from interlocking of individual wall components will depend on the specific wall type. Usually, interlocking resistance between wall components is provided by the wall supplier.

For wall corners not cast monolithically, a special facing unit formed to go across the corner should be used to provide continuity and stability across a continuous corner vertical joint. Historically, corners and abrupt alignment changes in walls have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This should be considered when designing and detailing a wall corner for seismic loading. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

### 11.11.7—Abutments

Abutment seats constructed on modular units shall be designed by considering earth pressures and supplemental horizontal pressures from the abutment seat beam and earth pressures on the backwall. The top module shall be proportioned to be stable under the combined actions of normal and supplementary earth pressures. The minimum width of the top module shall be

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

6.0 ft. The centerline of bearing shall be located a minimum of 2.0 ft from the outside face of the top precast module. The abutment beam seat shall be supported by, and cast integrally with, the top module.

The front face thickness of the top module shall be designed for bending forces developed by supplemental earth pressures. Abutment beam-seat loadings shall be carried to foundation level and shall be considered in the design of footings.

Differential settlement provisions, specified in Article 11.10.4, shall apply.

### 11.11.8—Drainage

In cut and side-hill fill areas, prefabricated modular units shall be designed with a continuous subsurface drain placed at, or near, the footing grade and outletted as required. In cut and side-hill fill areas with established or potential groundwater levels above the footing grade, a continuous drainage blanket shall be provided and connected to the longitudinal drain system.

For systems with open front faces, a surface drainage system shall be provided above the top of the wall.

## 11.12—SOIL NAIL WALLS

### 11.12.1—General Considerations

Soil nail walls, illustrated in Figure 11.12.1-1, most commonly consist of: (a) a soil nail (i.e., steel bar) that is placed in a pre-drilled hole, then grouted along its entire length in the hole; (b) connectors in the soil nail head; and (c) a structurally-continuous reinforced shotcrete or concrete cover (facing) connecting all nail heads.

The feasibility of using a soil nail wall at a particular location should be based on the suitability of the soil and rock conditions at both the wall face and along the length of the nails. Where fill is to be placed above the soil nail wall, or if the wall supports a combination of cut and fill, the fill placed near the wall face should be limited regarding depth of fill placed below the wall top to no more than down to the first row of nails, and the placement and compaction of the fill shall not damage the nails or facing or otherwise compromise the ability of these elements to resist load.

**C11.12.1**

Soil nail walls are top-down construction structures that are particularly well suited for ground conditions that require vertical or near-vertical cuts, and may be used for both permanent and temporary support. Favorable ground conditions make soil nailing technically feasible and cost effective, compared with other techniques, when:

- the soil being excavated is able to stand unsupported, 3.0 to 6.0 ft high, vertically or near vertical, for 1 to 2 days;
- all soil nails are above the groundwater table; and
- the long-term integrity of the soil nails can be maintained through corrosion protection.

If the soil nail wall retains fill in the upper part of the wall, provisions to protect against nail and facing damage resulting from backfill and subsoil settlement, or backfill and compaction activities above the anchors, should be included.

Soil nail walls may also be feasible to stabilize marginally unstable existing slopes in which a sufficient length of nails can penetrate behind the failure zone and in which the wall installation process will not exacerbate, temporarily or permanently, the stability problem.

The availability or ability to obtain underground easements and proximity of buried facilities to nail locations should also be considered in assessing feasibility.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Horizontal nail spacing, $S_h$, is typically the same as vertical nail spacing, $S_v$, and is typically between 4.0 ft and 6.5 ft, with a maximum influence area of $S_h \times S_v \leq 40.0$ ft$^2$. Soil nail spacing may be modified to accommodate the presence of existing underground structures or utilities behind the wall.

Subsurface conditions that are generally well-suited for soil nail applications include dense to very dense granular soils with apparent cohesion; weathered rock without adverse planes of weakness; stiff to hard fine-grained soils; engineered fill; some residual soils; and some glacial till soils.

Examples of unfavorable soil types and ground conditions include dry, poorly-graded cohesionless soils; granular soils with high groundwater; soils with cobbles and boulders; soft to very soft fine-grained soils; collapsible soils; organic soils; highly-corrosive soils; weathered rock with unfavorable planes of weakness; karstic formations; loess; and expansive soils.

Corrosion protection is provided by grouting, epoxy coating, galvanized coating, and encapsulation, or a combination of these methods (not shown in Figure 11.12.1-1). See Article 11.12.8 and FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015) for corrosion protection design considerations.

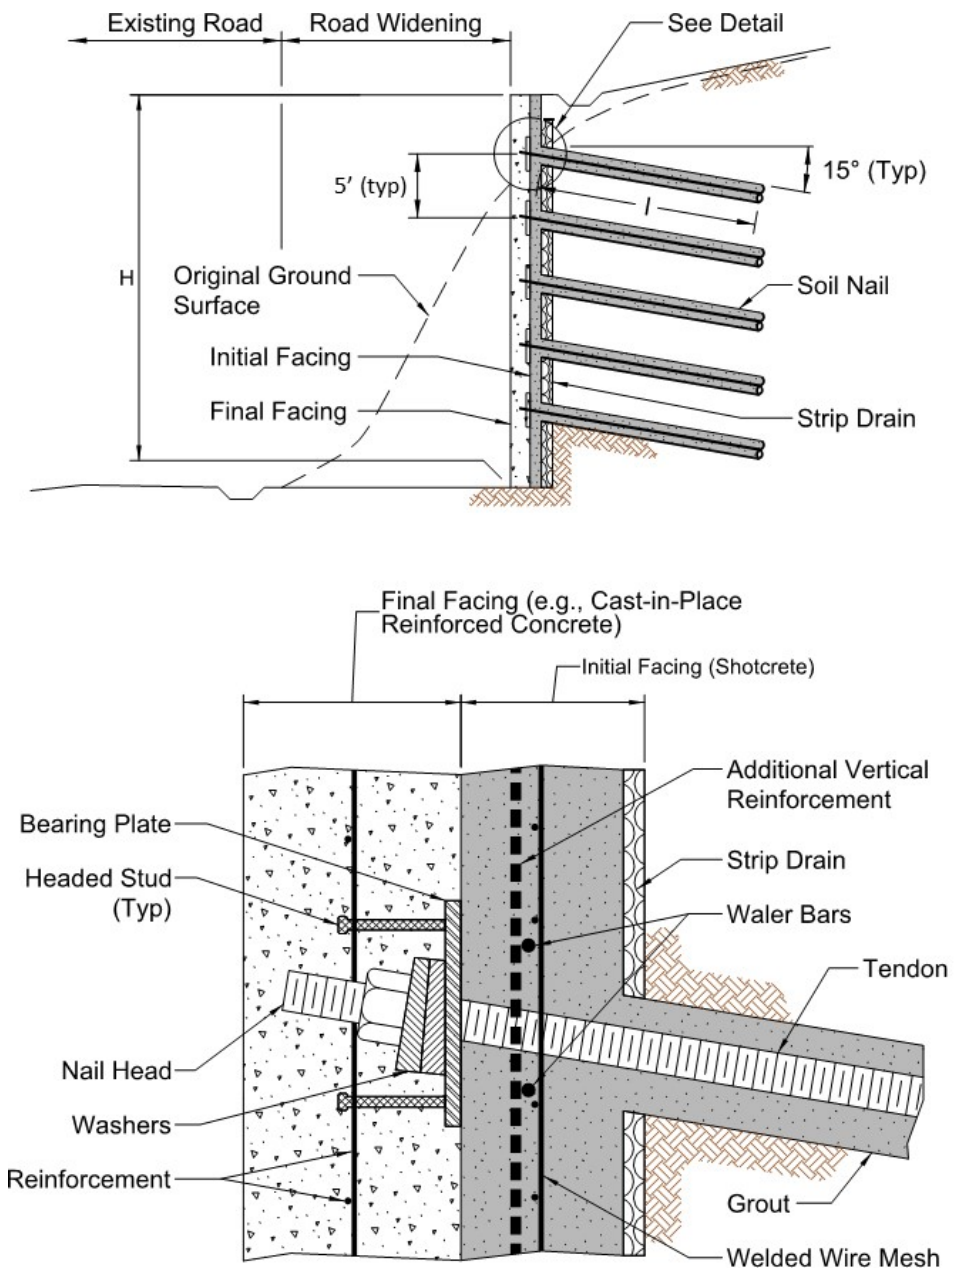

**Figure 11.12.1-1—Typical Cross-Section of a Soil Nail Wall: (a) Overall Cross-Section, and (b) Nail Head Detail. (Lazarte et al., 2015, after Porterfield et al., 1994)**

### 11.12.2—Loading

The provisions of Article 11.6.1.2 shall apply.

Limit equilibrium analysis methods shall be used to assess wall loading and stability for final design. When additional surcharge loads, such as a structure footing load or live load, are applied to the top of the reinforced zone of the soil nail wall, they are factored as specified in Article 3.4.1 for the Strength I Limit state.

### C11.12.2

For soil nail walls, the limit equilibrium slope stability analyses to assess overall stability (external to the nail reinforced section) and to determine nail loads (i.e., $T_{maxsn}$, the maximum soil nail force in each soil nail row determined from the limit equilibrium stability analysis) for internal and compound stability (i.e., nail tensile design, nail pullout, and facing design) are as illustrated in Figure C11.12.2-1. Determination of $T_{maxsn}$ for internal and compound stability for nail tensile resistance, pullout, and facing design is done at the strength limit state, and if extreme events such as seismic

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

are being considered, $T_{maxsn}$ is estimated also considering the additional loads applicable to the extreme event being considered.

Available soil nail wall analysis computer programs analyze soil nail tension and pullout as a single design step to achieve a target minimum level of safety. The tension in the nails, $T_{maxsn}$, is determined at the target soil failure resistance factor (see Articles 11.5.7 and 11.6.3.7) for the wall (i.e., 1/*FS* output by the computer program, in which *FS* is typically 1.3 or 1.5). Reduction factors (also termed "safety factors") are applied to soil nail tensile and pullout resistance to account for variability in the pullout and nail tensile resistance. See Lazarte et al. (2015) for additional guidance on the application of typical soil nail wall design programs to an LRFD framework.

Available computer programs used for soil nail wall stability analysis typically provide values of $T_{maxsn}$ in each soil nail row that correspond to the target level of safety. The $T_{maxsn}$ values obtained may vary depending on the volume of soil between the wall face and the critical surface (which is a function of the slope stability *FS*), the type of surface analyzed (e.g., circular, log spiral, two-part wedge, etc.), and the distribution of force along the length of the nails. How these factors affect the results may vary depending on the software used for the wall design. The designer should consider these factors when selecting values for $T_{maxsn}$ to be used in the limit state equations specified in Articles 11.12.5 and 11.12.6 for designing the nails for tensile and pullout resistance, and the strength of the facing needed.

The load and resistance factors specified for use for nail pullout (Article 11.12.5.2), nail tensile resistance (Article 11.12.6.1), and facing design (Article 11.12.6.2) have been calibrated by fitting to past Allowable Stress Design (ASD) practice. For example, for ASD pullout resistance, a slope stability *FS* of 1.3 was used, and the nominal pullout resistance was reduced by an *FS* of 2.0. For the LRFD limit state equations corresponding to this example, $T_{maxsn}$ values are obtained from the slope stability analysis using a soil failure resistance factor of 0.75 and load factor of 1.0, a load factor for vertical earth pressure applied to $T_{maxsn}$ of $\gamma_{EV}$ = 1.35, and a pullout resistance factor of 0.65. The equations produce a similar result as used in past ASD practice. Additional background information regarding the development of load and resistance factors for soil nail wall design is provided in Lazarte et al. (2015).

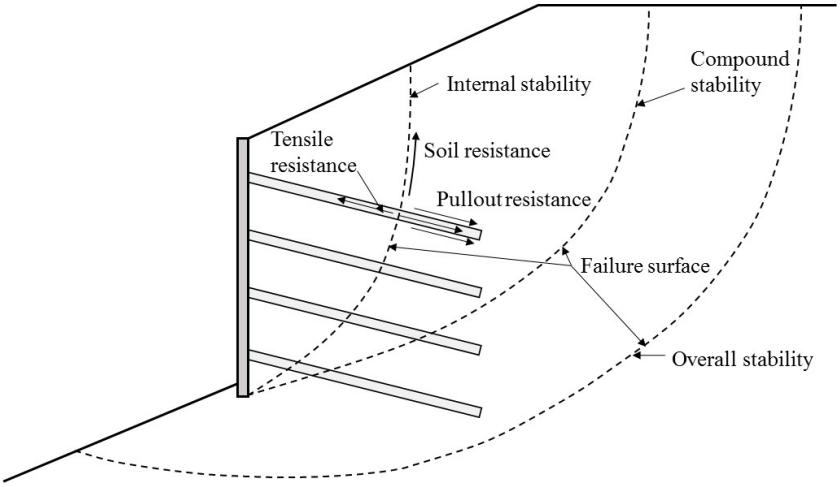

**Figure C11.12.2-1—Failure Modes in Soil Nail Walls**

### 11.12.3—Movement at the Service Limit State

The provisions of Articles 10.6.2.2, 10.7.2.2, and 11.8.3.1 shall apply as applicable.

The effects of wall movements on adjacent facilities shall be considered in the development of the wall design.

### C11.12.3

A first order estimate of horizontal and vertical displacements at the top of the wall can be estimated with the procedure presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015). Displacements are a function of the soil nail length to wall height ratio, soil nail spacing, wall batter, and soil conditions.

### 11.12.4—Safety against Soil Failure (External and Overall Stability—Strength Limit State)

#### 11.12.4.1—Sliding

The provisions of Article 10.6.3.4 shall apply.

#### 11.12.4.2—Overall Stability

The potential failure surfaces to be considered in overall stability should not intersect soil nails but instead go behind the ends of the nails. With regard to the minimum level of safety required, the provisions of Article 3.4.1 for load factors and Article 11.6.3.7 for soil resistance factors shall apply. For the case of failure surfaces intersecting soil nails, see Articles 11.12.2, 11.12.5, and 11.12.6.

Overall stability analyses should also be conducted for intermediate excavation conditions. For soil nail walls with complex geometry (e.g., multiple-tiered walls), the provisions of Article 11.10.4.3 shall apply.

#### C11.12.4.2

Overall stability of soil nail walls is commonly evaluated using two-dimensional limit-equilibrium-based methods. For this specific limit state, only failure surfaces that are behind the soil nails are considered. Failure surfaces that intersect one or more nail rows, including both surfaces that are defined as compound stability and those that intersect all the nail rows (Figure C11.12.2-1) are addressed in the Strength Limit State for internal wall stability. Detailed guidance for evaluating the overall stability of soil nail walls, including intermediate excavation conditions, and for defining nominal tensile and pullout forces in the soil nails is provided in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

## 11.12.5—Safety against Soil Failure (Internal and Compound Stability—Strength Limit State)

### 11.12.5.1—Soil Shear Strength

As specified in Article 11.12.2, limit equilibrium analyses shall be conducted to assess internal and compound stability of soil nail walls in the Strength Limit State. If the wall supports a structural element, the load applied to the wall by the structural element should be factored as specified in Article 3.4.1 for the Strength I Limit state. With regard to the minimum level of safety required, the provisions of Article 11.6.3.7 for soil resistance factors shall apply.

### C11.12.5.1

See Article C11.12.2 for background on limit equilibrium analysis procedures for soil nail walls. As discussed in that article, the resistance of the soil (i.e., its shear strength) is handled separately from LRFD analysis of the nails.

While compound stability is in a sense both internal and external, because the failure surface involves the resistance of the structural elements (i.e., nails), this limit state is dealt with in the Strength Limit State. The resistance of the nails in pullout and as tensile members is assessed as specified in Articles 11.12.5.2 and 11.12.6.1.

### 11.12.5.2—Soil Nail Pullout

Soil nails shall be designed to resist pullout of the length of nail extending beyond the critical failure surface. It shall be verified that the factored pullout resistance available is sufficient to obtain the desired minimum level of safety as specified in Articles 11.12.2 and 11.12.5.1, and as further described in Articles C11.12.2 and C11.12.5.1. The following shall be verified for each row of nails, considering both internal and compound stability:

$$\phi_{PO} R_{PO} \geq \gamma_{p-EV} T_{maxsn} \qquad (11.12.5.2\text{-}1)$$

where:

$R_{PO}$ = nominal pullout resistance (kip)
$\phi_{PO}$ = resistance factor for soil nail pullout (dim.)
$\gamma_{p\text{-}EV}$ = the maximum load factor for vertical earth pressure, *EV*, from Table 3.4.1-2 (dim.).
$T_{maxsn}$ = maximum soil nail force determined from the limit equilibrium stability analysis in Article 11.12.2 (kip)

Variables for pullout are illustrated in Figure 11.12.5.2-1.

The nominal pullout resistance, $R_{po}$ (kips), shall be computed as:

$$R_{PO} = \pi q_u D_{DH} L_P \qquad (11.12.5.2\text{-}2)$$

where:

$R_{PO}$ = nominal pullout resistance (kip)
$q_u$ = bond strength per unit area (ksf)
$D_{DH}$ = drill hole diameter (ft)
$L_P$ = the length of soil nail behind the critical failure surface (ft)

### C11.12.5.2

A uniform distribution of bond stresses along the pullout length behind the critical failure surface, $L_P$, is assumed.

When using the pullout limit state Eqs. 11.12.5.2-1 and 11.12.5.2-2, $L_p$ is usually determined using the critical failure surface from the final wall configuration.

Soil nail bond strength is influenced by soil or rock type, overburden stress, drilling method, drill hole cleaning, grouting procedure, and grout characteristics. As a guide, the presumptive values in Tables C11.12.5.2-1 and C11.12.5.2-2 may be used to estimate the bond strength for different drilling methods and to estimate the bond strength for gravity-grouted in coarse-grained and fine-grained soils, respectively. Presumptive bond strength values in weathered rock and in rock, for rotary drilling method, are provided in Table C11.12.5.2-3.

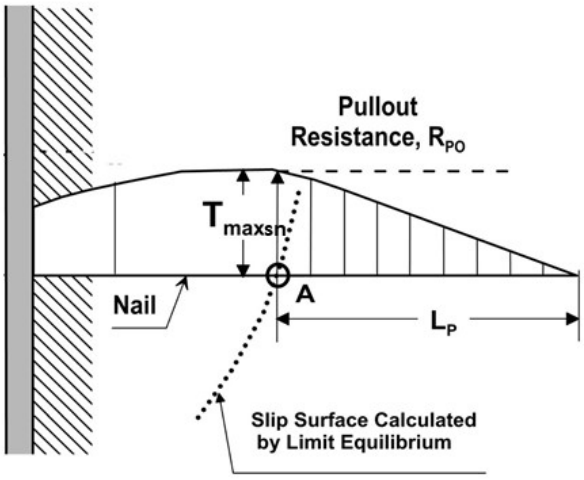

**Figure 11.12.5.2-1—Definition of Pullout Variables**

**Table C11.12.5.2-1—Presumptive Bond Strength for Soil Nails in Coarse-Grained Soils (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al., 2015; after Elias and Juran, 1991)**

| Drilling Method | Soil Type | Bond Strength, $q_u$ (psi) |
|---|---|---|
| Rotary Drilled | Sand/Gravel | 15–26 |
| Rotary Drilled | Silty Sand | 15–22 |
| Rotary Drilled | Silt | 9–11 |
| Rotary Drilled | Piedmont Residual | 6–17 |
| Rotary Drilled | Fine Colluvium | 11–22 |
| Driven Casing | Sand/Gravel w/ low overburden (1) | 28–35 |
| Driven Casing | Sand/Gravel w/ high overburden (1) | 41–62 |
| Driven Casing | Dense Moraine | 55–70 |
| Driven Casing | Colluvium | 15–26 |
| Augered | Silty Sand Fill | 3–6 |
| Augered | Silty Fine Sand | 8–13 |
| Augered | Silty Clayey Sand | 9–20 |

Note: (1) Low and high overburden are defined as effective overburden pressure being, respectively, less than and greater than 1.5 tsf.

**Table C11.12.5.2-2—Presumptive Bond Strength for Soil Nails in Fine-Grained Soils (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al., 2015; after Elias and Juran, 1991)**

| Drilling Method | Soil Type | Bond Strength, $q_u$ (psi) |
|---|---|---|
| Rotary Drilled | Silty Clay | 5–7 |
| Driven Casing | Clayey Silt | 13–20 |
| Augered | Loess | 4–11 |
| Augered | Soft Clay | 3–4 |
| Augered | Stiff Clay | 6–9 |
| Augered | Stiff Clayey Silt | 6–15 |
| Augered | Calcareous Sandy Clay | 13–20 |

**Table C11.12.5.2-3—Presumptive Bond Strength for Soil Nails in Rock (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al. 2015; after Elias and Juran 1991)**

| Rock Type | Bond Strength, $q_u$ (psi) |
|---|---|
| Marl/Limestone | 44–58 |
| Phyllite | 15–44 |
| Chalk | 73–87 |
| Soft Dolomite | 58–87 |
| Fissured Dolomite | 87–145 |
| Weathered Sandstone | 29–44 |
| Weathered Shale | 15–22 |
| Weathered Schist | 15–25 |
| Basalt | 73–87 |
| Slate/Hard Shale | 44–58 |

The use of the current value of *EV* in Table 3.4.1-2 (referred to in this Section as $\gamma_{p\text{-}EV}$) for the load factor in this case should be considered an interim measure until research is completed to quantify load prediction bias and uncertainty.

## 11.12.6—Safety against Structural Failure (Internal and Compound Stability—Strength Limit State)

### 11.12.6.1—Soil Nail in Tension

It shall be verified that the factored soil nail tensile resistance available is sufficient to obtain the desired minimum level of safety as specified in Articles 11.12.2 and 11.12.5.1, and as further described in Articles C11.12.2 and C11.12.5.1. Therefore, the following limit state shall be verified for each row of nails, considering both internal and compound stability:

$$\phi_T R_T \geq \gamma_{p-EV} T_{maxsn} \qquad (11.12.6.1\text{-}1)$$

where:

$\phi_T$ = resistance factor for bar in tension from Table 11.5.7-1 (dim.)
$R_T$ = nominal tensile resistance of bar (kip)
$\gamma_{P\text{-}EV}$ = the maximum load factor for vertical earth pressure, *EV*, from Table 3.4.1-2 (dim.)
$T_{maxsn}$ = maximum soil nail force determined from the limit equilibrium stability analysis in Article 11.12.2 (kip)

The nominal tensile resistance of a soil nail bar shall be computed as:

**C11.12.6.1**

The use of the current value of *EV* in Table 3.4.1-2 (referred to in this Section as $\gamma_{p\text{-}EV}$) for the load factor in this case should be considered an interim measure until research is completed to quantify load prediction bias and uncertainty.

The contribution of the grout to the nominal resistance in tension should be disregarded.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$R_T = A_t f_y \qquad (11.12.6.1\text{-}2)$$

where:

$A_t$ = cross-sectional area of soil nail bar ($in^2$)
$f_y$ = yield strength of steel (ksi)

### 11.12.6.2—Soil Nail Wall Facing—Strength Limit State

*11.12.6.2.1—General*

The failure modes of the facing of a soil nail wall that shall be considered include: (a) flexure (i.e., bending); (b) punching shear; and (c) headed stud in tension. These failure modes are shown schematically in Figure 11.12.6.2.1-1. Nail loads used as part of the facing system analysis are determined as specified in Article 11.12.2 considering both internal and compound stability, assuming that $T_{osn}$, the load in the soil nail at the nail head, is equal to $T_{maxsn}$.

*C11.12.6.2.1*

The failure modes for flexure and punching shear in the facing shall be considered separately for the temporary and the permanent facing. The failure mode for tension in the headed stud shall be considered only in permanent facings.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

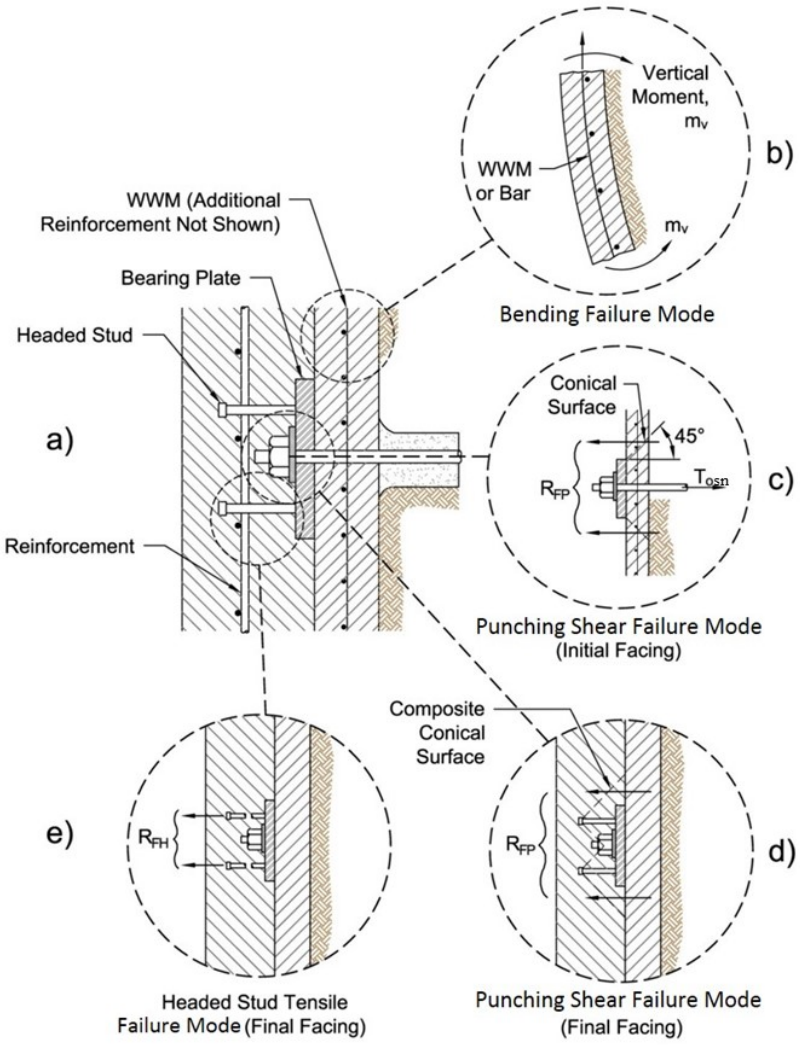

**Figure 11.12.6.2.1-1—Failure Modes to be Considered in Soil Nail Wall Facings: (a) Typical Section, (b) Flexure for Both Initial and Final Facing; (c) Punching Shear in Initial Facing; (d) Punching Shear in Final Facing; and (e) Headed stud in Tension**

*11.12.6.2.2—Facing Flexure*

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.12.2, for flexure in the facing, the following equation shall be satisfied:

$$\phi_{FF} R_{FF} \geq \gamma_{p-EV} T_{osn} \qquad (11.12.6.2.2\text{-}1)$$

in which:

$\phi_{FF}$ = resistance factor for flexure in the facing from Table 11.5.7-1 (dim.)
$R_{FF}$ = flexural resistance of facing (kip)
$T_{osn}$ = tensile force at the nail head (kip)

*C11.12.6.2.2*

The nominal resistance for flexure in the facing depends on the soil pressures mobilized behind the facing, horizontal and vertical soil nail spacing, soil conditions, and facing stiffness. The pressure distribution acting on the facing can be nonuniform, with load concentrating near the soil nail and decreasing toward the midpoint between the nails. See Lazarte et al. (2015) for a more in-depth explanation of the pressure distribution behind the soil nail wall facing. $C_F$ is used to account for this nonuniformity.

Reinforcement can be welded wire mesh (WWM) or concrete reinforcement bars.

See FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015) for guidance on minimum and maximum

All rights reserved. Duplication is a violation of applicable law.

$R_{FF}$ shall be estimated using the following equations:

$$R_{FF} = 3.8 C_F f_y F \qquad (11.12.6.2.2\text{-}2)$$

This equation is valid for shotcrete with $f'_c \geq 4{,}000$ psi.

$$F = smaller\ of \left\{ \frac{\left(a_{vm} + a_{vn}\right) \times \left(\frac{S_H}{S_V} h\right)}{\left(a_{hm} + a_{hn}\right) \times \left(\frac{S_V}{S_H} h\right)} \right. \qquad (11.12.6.2.2\text{-}3)$$

where:

$C_F$ = factor to consider nonuniform soil pressures behind soil nail wall facing (dim) see Table 11.12.6.2.2-1

$h$ = nominal facing thickness, $h_i$ for initial facing or $h_f$ for final facing (ft)

$a_{vn}$ = cross-sectional area of vertical reinforcement per unit width direction, at nail head (in.$^2$/ft); see Table 11.12.6.2.2-2

$a_{vm}$ = cross-sectional area vertical reinforcement per unit width at midspan (in.$^2$/ft); see Table 11.12.6.2.2-2

$a_{hn}$ = cross-sectional area of horizontal reinforcement per unit width at nail head (in.$^2$/ft); see Table 11.12.6.2.2-2

$a_{hm}$ = cross-sectional area of horizontal reinforcement per unit width at midspan (in.$^2$/ft); see Table 11.12.6.2.2-2

**Table 11.12.6.2.2-1—Factor, $C_F$**

| Facing Layer | Nominal Facing Thickness, $h_i$ or $h_f$ (in.) | Factor, $C_F$ |
|---|---|---|
| Initial | 4 | 2.0 |
| | 6 | 1.5 |
| | 8 | 1.0 |
| Final | All | 1.0 |

The cross-sectional areas of reinforcement per unit width in the vertical or horizontal direction and around and in-between nails are shown schematically in Figure 11.12.6.2.2-1.

Reinforcement areas per unit width shall be determined as summarized in Table 11.12.6.2.2-2.

amount of steel reinforcement ratio, $\rho_{ij}$, expressed as a percentage, to be placed at different locations of the facing. The reinforcement ratio is defined as:

$$\rho_{ij} = \frac{a_{ij}}{0.5\ h} \times 100 \qquad (C11.12.6.2.2\text{-}1)$$

Where $a_{ij}$ can take the values of $a_{vm}$, $a_{vn}$, $a_{hm}$, or $a_{hn}$; and $h$ can take the values of $h_i$ or $h_f$.

With regard to Eqs. 11.12.6.2.2-2 and 11.12.6.2.2-3, more general equations are provided in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**Table 11.12.6.2.2-2—Facing Reinforcement Area per Unit Width**

| Direction | Location | Cross-Sectional Area of Reinforcement per Unit Width |
|---|---|---|
| Vertical | Nail Head (1) | $a_{vn} = a_{vm} + \frac{A_{VH}}{S_H}$ |
| | Midspan | $a_{vm}$ |
| Horizontal | Nail Head (2) | $a_{hn} = a_{hm} + \frac{A'_{HN}}{S_V}$ |
| | Midspan | $a_{hm}$ |

Notes:

(1) At the nail head, the total cross-sectional area (per unit length) of reinforcement is the sum of the welded-wire mesh area ($a_{vm}$) and the area of additional vertical bars ($A'_{VH}$) divided by the horizontal spacing ($S_h$).

(2) At the nail head, the total area is the sum of the area of the welded-wire mesh ($a_{hm}$) and the area of additional horizontal bars (i.e., waler bars, $A'_{HN}$) divided by $S_v$.

If (vertical) bars are used behind the nail heads, the total reinforcement area per unit length in the vertical direction shall be calculated as:

$$a_{vn} = a_{vm} + \frac{A'_{VH}}{S_H} \qquad (11.12.6.2.2\text{-}4)$$

where:

$A'_{VH}$ = equivalent cross-sectional area at the head in the vertical direction (in.$^2$)

Similarly, this concept should be applied if additional horizontal rebar (i.e., waler bars) is used. The total reinforcement area per unit length in the horizontal direction shall then be calculated as:

$$a_{hn} = a_{hm} + \frac{A'_{HN}}{S_V} \qquad (11.12.6.2.2\text{-}5)$$

$A'_{HN}$ = equivalent cross-sectional area at the head in horizontal direction (in.$^2$)

All rights reserved. Duplication is a violation of applicable law.

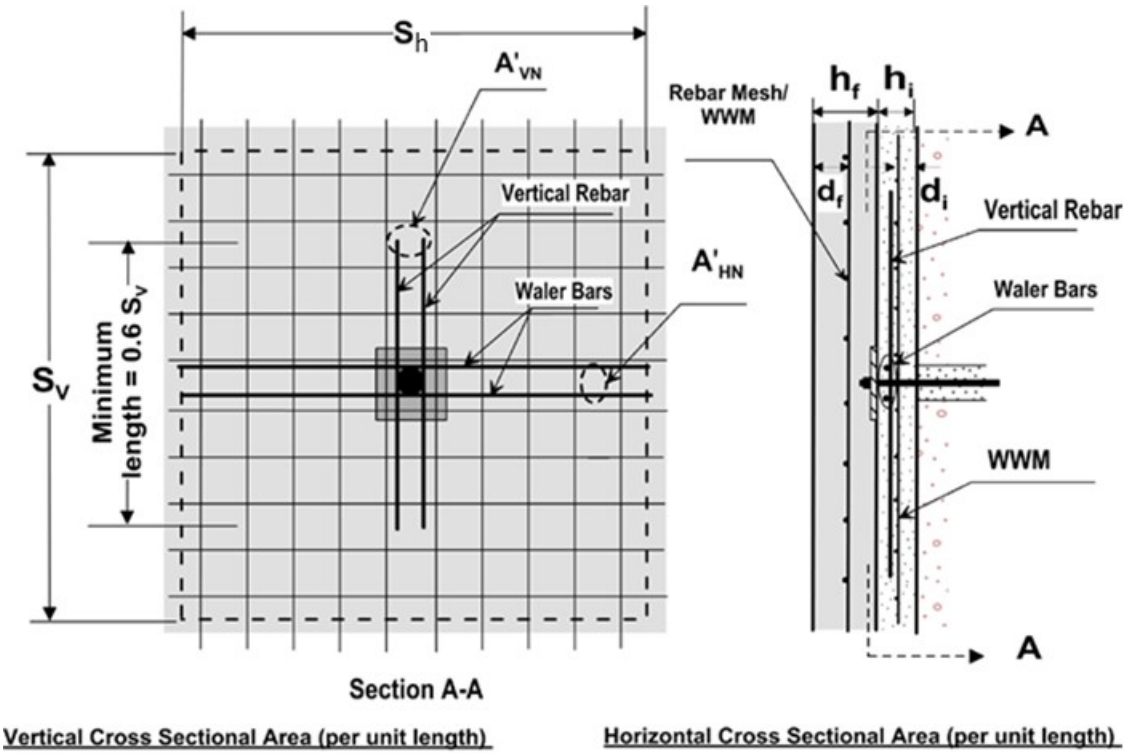

**Figure 11.12.6.2.2-1—Geometry used for Flexural Failure Mode**

*11.12.6.2.3—Facing Punching Shear Resistance*

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.12.2, for punching shear in the facing, it shall be verified that:

$$\phi_{FP} R_{FP} \geq \gamma_{p-EV} T_{osn} \qquad (11.12.6.2.3\text{-}1)$$

where:

$\phi_{FP}$ = resistance factor for punching shear in facing (dim)
$R_{FP}$ = nominal punching shear resistance of facing (kip)

in which:

$$R_{FP} = C_P V_F \qquad (11.12.6.2.3\text{-}2)$$

where:

$V_F$ = punching shear force acting through facing (kip)
$C_P$ = correction factor to account for contribution of soil support (dim). $C_p$ should normally be assumed to be 1.0.

The nominal punching shear resistance shall be calculated as:

*C11.12.6.2.3*

The failure mode for punching shear may involve the formation of a localized, conical failure surface around the nail head. The failure surface may extend behind the bearing plate or headed studs and may punch through the facing thickness at an inclination of about 45 degrees and form two punching failure surfaces (Figure 11.12.6.2.3-1).

The size of the conical failure surfaces depends on the facing thickness and the type of the nail-facing connection (i.e., bearing plate or headed studs).

Generally, the contribution from the soil support is ignored and, $C_P$ = 1.0. If the soil reaction is considered, $C_P$ can have values up to 1.15.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$V_F = 18.34\sqrt{f'_c}\pi D'_c h_c \qquad (11.12.6.2.3\text{-}3)$$

where:

$f'_c$ = compressive strength of concrete (ksi)
$D'_c$ = effective equivalent diameter of conical surface at soil nail head (ft)
$h_c$ = effective depth of conical surface (ft)

For the initial facing:

$$D'_c = L_{BP} + h_c \qquad (11.12.6.2.3\text{-}4)$$

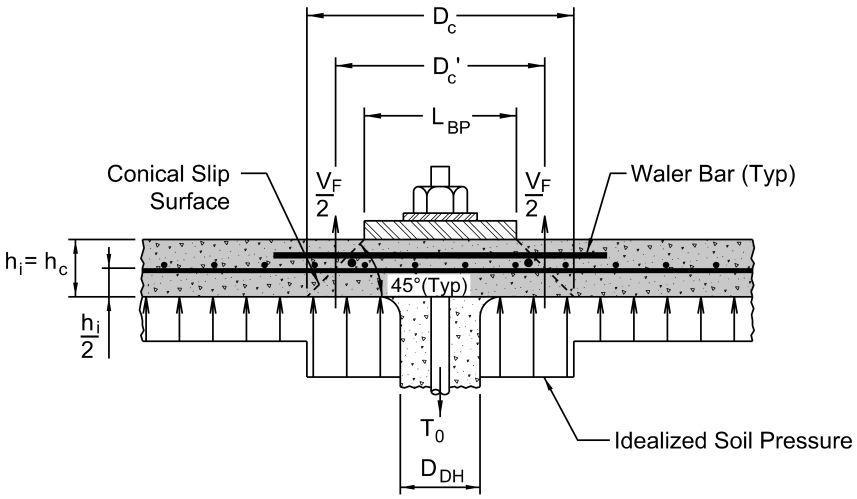
where:

$L_{BP}$ = length of the bearing plate (ft)

For the final facing:

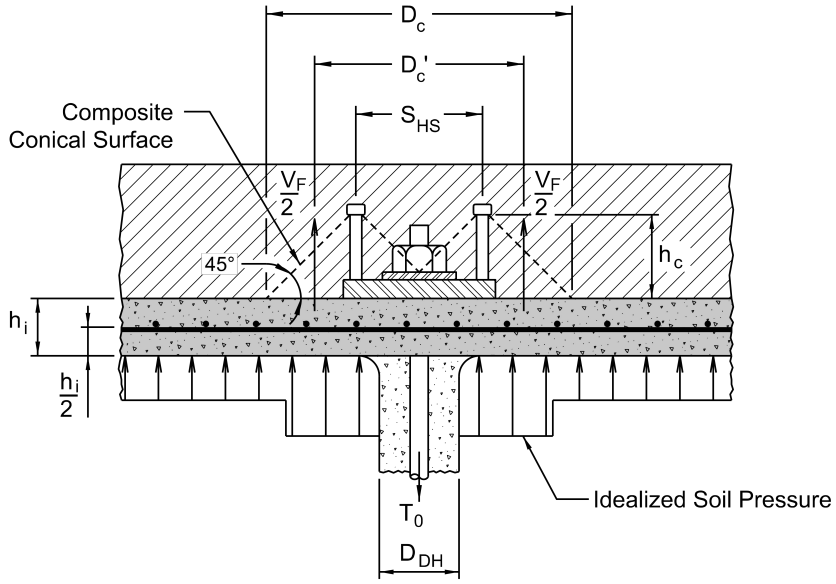
$$D'_c = smaller\ of \begin{cases} S_{HS} + h_c \\ 2h_c \end{cases} \qquad (11.12.6.2.3\text{-}5)$$

where:



$S_{HS}$ = spacing of the headed studs

These equations shall be separately used to design initial and final facing. The maximum and average diameters of the failure surface ($D_c$ and $D'_c$ on Figure 11.12.6.2.3-1), as well as the effective depth of the failure surface, $h_c$, shall be selected separately for initial and final facings.



For initial facings, only the dimensions of the bearing plate and facing thickness should be considered. For final facings, the dimensions of headed studs, bearing plate, and the facing thickness shall be considered.

Typical dimensions for bearing plates and headed studs can be found in FHWA-NHI-14-007/ FHWA GEC 7 (Lazarte et al., 2015).

(a) Bearing Plate Connection

(b) Headed Stud Connection

**Figure 11.12.6.2.3-1—Punching Shear Failure Modes**

*11.12.6.2.4—Headed Stud in Tension*

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.2.2, for design of the facing headed stud in tension, it shall be verified that:

$$\phi_{FH} R_{FH} \geq \gamma_{p-EV} T_{osn} \qquad (11.12.6.2.4\text{-}1)$$

where:

$\phi_{FH}$ = resistance factor for headed stud in tension (dim)

$R_{FH}$ = nominal tensile resistance of headed stud (kip)

*C11.12.6.2.4*

To provide sufficient anchorage, the length of the headed studs shall extend beyond the midsection of the facing, while maintaining 2.0 in. minimum cover.

When threaded bolts are used in lieu of headed stud connectors, the effective cross-sectional area of the bolts must be employed in Eqs. 11.12.6.2.4-2, 11.12.6.2.4-3, and 11.12.6.2.4-4. See FHWA-NHI-14-007/ FHWA GEC 7 (Lazarte et al., 2015) for computation of the effective cross-sectional area of threaded anchors.

in which:

$$R_{FH} = N_H A_S f_{y\text{-}hs} \qquad (11.12.6.2.4\text{-}2)$$

where:

$N_H$ = number of headed studs in the connection (dim)
$A_S$ = cross-sectional area of the shaft of a headed stud (in.$^2$)
$f_{y\text{-}hs}$ = minimum yield stress of headed stud (ksi)

In addition, it should be verified that:

$$A_H \geq 2.5 A_S \qquad (11.12.6.2.4\text{-}3)$$

$$t_{SH} \geq 0.5 \left( D_{SH} - D_{SC} \right) \qquad (11.12.6.2.4\text{-}4)$$

where (see Figure 11.12.6.2.4-1):

$A_H$ = cross-sectional area of the stud head (in.$^2$)
$t_{SH}$ = head thickness (in.)
$D_{SH}$ = diameter of the stud head (in.)
$D_{SC}$ = diameter of the headed stud shaft (in.)

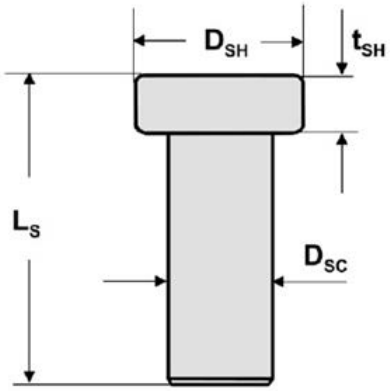

**Figure 11.12.6.2.4-1—Geometry of a Headed Stud**

### 11.12.7—Seismic Design of Soil Nail Walls

Soil nail walls shall be designed for seismic loads when applicable. Article 11.5.4.2 defines when earth-retaining structures require analysis for loads at the Extreme Event I limit state. The criteria for MSE walls, another earth-supporting system regarded as flexible, is considered appropriate for soil nail walls.

#### 11.12.7.1—External and Global Stability

External stability of soil nail walls for seismic loading conditions shall be conducted as specified in Article 11.6.5 except as modified in Article 11.10.7.1 for MSE walls for sliding stability. For global stability, a

### C11.12.7

Soil nail seismic resistance factors, for use with MSE wall seismic design criteria, are presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

horizontal seismic coefficient, per Article 11.6.5, shall be incorporated into the limit equilibrium analysis.

**11.12.7.2—Internal Stability**

Internal stability of soil nail walls for seismic loading conditions shall be performed by incorporating a horizontal seismic coefficient, per Article 11.6.5, into the limit equilibrium analysis to quantify nominal soil nail tensile load under seismic loading. Resistance factors for internal stability for seismic conditions shall be as follows:

- Bar pullout – 0.65
- Bar rupture
  - Bar grades 60–80 (AASHTO M 31M/M 31) – 0.75
  - Bar grade 150 (AASHTO M 275M/M 275) – 0.65
  - Facing flexure resistance – 0.90
  - Facing punching shear – 0.90
  - Headed stud in tension
    - A307 steel bolt – 0.65
    - A325 bolt – 0.75

**C.11.12.7.2**

Limit equilibrium slope stability analyses are used to quantify the nominal tensile load under seismic loads in the soil nail bars.

**11.12.8—Corrosion Protection**

For all permanent soil nail walls and, in some cases, for temporary walls, the soil corrosion potential shall be evaluated and considered part of the design.

Soils shall typically be considered nonaggressive if the soils meet all of the following criteria:

- pH = 5 to 10
- Resistivity ≥ 3,000 ohm-cm
- Chlorides ≤ 100 ppm
- Sulfates ≤ 200 ppm
- Organic Content ≤ 1 percent by weight

Soils not meeting one or more of these criteria shall be considered to be aggressive. If the resistivity is greater than or equal 5,000 ohm-cm, the chlorides and sulfates requirements may be waived.

The primary corrosion protection depends on the aggressiveness of the in-situ soils. Two classes of corrosion protection shall be used.

- Class A—Bar Encapsulation
- Class B—Epoxy-coated or galvanized bars

Class A bar encapsulation shall consist of providing either a 40-mil thickness PVC or 60-mil thickness HDPE corrugated sheath. The sheath shall have a minimum diameter of the bar plus 0.4 in. Place the sheath around the bar and grout the annular space between the bar and

**C11.12.8**

An in-depth discussion on corrosion of metallic components used to construct soil nail walls is provided in FHWA-NHI-14-007/FHWA GEC 7, *Soil Nail Walls* (Lazarte et al., 2015).

The criteria provided for assessing corrosion potential are based on Elias et al., 2009.

Recommended test methods for soil chemical property determination include AASHTO T 289 for pH, AASHTO T 288 for resistivity, AASHTO T 291 for chlorides, AASHTO T 290 for sulfates, and AASHTO T 267 for organics.

Resistivity should be determined under the most adverse condition (i.e., a saturated state) in order to obtain a resistivity that is independent of seasonal and other variations in soil-moisture content (Elias et al., 2009).

A nonaggressive site does not mean that no corrosion will occur. Rather, for a nonaggressive site, a tolerable level of corrosion over the life of the structure should be expected, provided that the electro-chemical characteristics of the site do not change over the life of the structure.

Class A corrosion protection is used for sites that are considered aggressive or if the electro-chemical environment is unknown or not adequately defined. Class B corrosion protection is used for sites that are considered nonaggressive. However, Class A corrosion protection

the sheath. The grout cover shall be a minimum of 0.2 in. on all sides of the bar. See Figure 11.12.8-1.

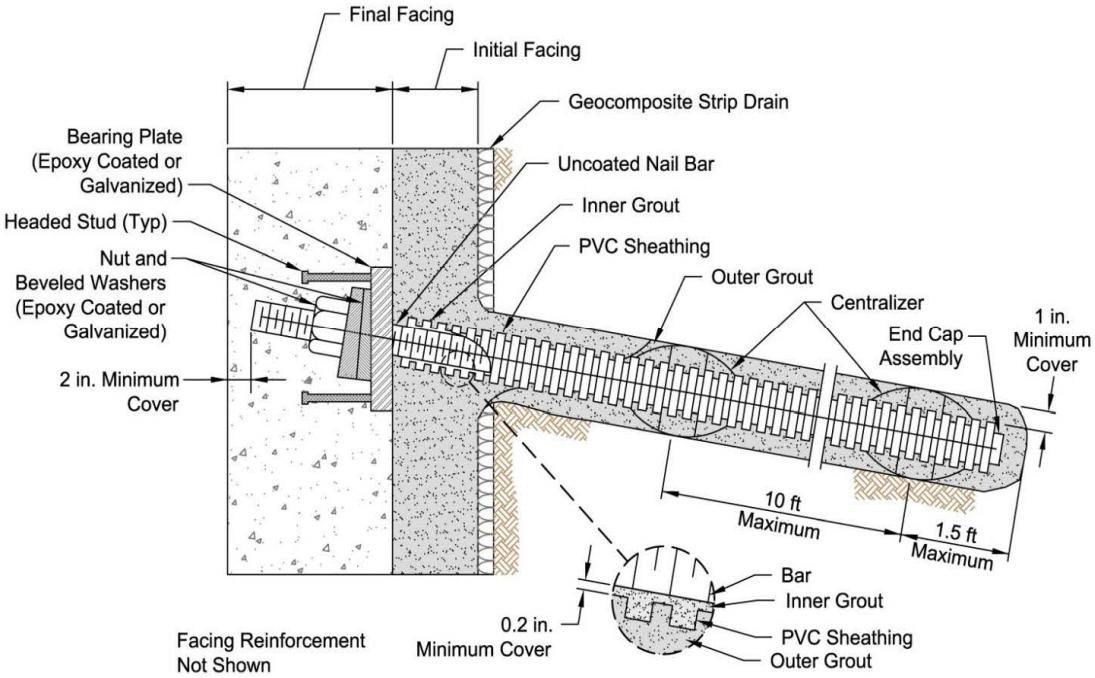

**Figure 11.12.8-1—Bar Encapsulation (Lazarte et al., 2015)**

Class B corrosion protection consists of epoxy coating and/or galvanization. The epoxy coating on the bars, plates, washers, and nuts shall have a required thickness ranging from 7 to 12 mils.

The other Class B corrosion protection is galvanization (i.e., zinc coating). The minimum galvanization that should be applied is 2.0 oz/ft$^2$ or 3.4-mil thickness. The galvanization of the bar shall adhere to the requirements of AASHTO M 111M/M 111 (ASTM A123/A123M). The plates, nuts, and washers shall be galvanized to the requirements of ASTM A153.

The minimum grout cover around the bar shall be 1 in. to provide a secondary level of corrosion protection. This minimum cover shall account for the sag of the bar between centralizers.

may be used for nonaggressive sites at the discretion of the Owner.

The epoxy coating is applied as required in ASTM A775 or A934.

The epoxy coatings used on the bars are color-coded green, gray, or purple. The green epoxy coating meets ASTM A775 and is used due to its flexibility. Green epoxy coating is suitable for rebar that will be bent into different shapes. The gray and purple epoxy coatings are less flexible, but have greater chemical resistance. The purple epoxy coating is better suited for marine or harsh environments.

ASTM A123 requires a minimum average galvanization thickness of 3.4 mil for all bars on the project and a minimum of 3.1 mil on any individual bar. The zinc coating provides a sacrificial anode that corrodes while protecting the base metal.

The corrosion protection indicated applies only to customary rebar used as bars. The use of high-strength bars requires project-specific corrosion projection to be developed.

The use of sacrificial steel is not recommended as a corrosion protection method. However, if the Owner wants to use sacrificial steel as a corrosion protection method, see Lazarte et al., 2015 for the procedure.

### 11.12.9—Soil Nail Testing

Testing of soil nails shall be conducted to verify the bond strength, $q_u$, and nominal load transfer rate, $r_{po}$, between the soil and soil nail. This testing shall consist of, as a minimum, verification tests conducted on sacrificial nails installed and tested prior to production nail installation, and proof tests conducted during production nail installation. At least one verification test should be conducted in each soil unit encountered in the wall using the same installation technique and nail inclination as will be used for the production nails. Regarding proof tests, enough tests should be conducted in each nail row to account for the variability of the soil and the installation process.

### C11.12.9

During design, the bond strength should be estimated in accordance with Article 11.12.5.2, and as further described in Article C11.12.5.2 and used as input to conduct the soil nail wall design, from which the nail spacing and length are determined. Using that bond strength, the nominal load transfer rate, $r_{po}$, in units of load/unit length of nail can be determined for use in the construction contract documents.

The actual bond strength and load transfer rate are strongly dependent on the soil nail installation process. Hence, the verification and proof testing are used to confirm that $q_u$ and $r_{po}$ are obtained. Typically, a minimum of 5 percent of the nails in a nail row are proof tested, and for short rows, at least one nail should be proof tested. When selecting nails to proof test, consideration should be given to making sure that proof tests are conducted in all the geologic units. If some of the nails will be installed within ground water, some of the test nails located within the ground water should also be proof tested.

While the nominal load transfer rate applies to the entire nail length, it is most important that this load transfer rate is obtained behind the critical failure surface obtained from the limit equilibrium slope stability analyses used to design the wall. Test nails are usually installed to test a minimum bond length (typically 10.0 ft or more) to simulate the pullout resistance of the nail behind the critical failure surface. The bonded length of the test nail is grouted, while the remainder of the nail between the wall face and the nail bonded zone is left open. The bonded length of test nail should begin far enough away from the wall face such that the load carried by the grout–soil interface in the bonded zone is not unduly influenced by the presence of the reaction frame placed against the wall face during nail loading. Typically, a minimum of 3.0 to 5.0 ft between the wall face and the front of the bonded zone is required to accomplish this. If the portion of the test nail that is left open has a tendency to cave, a weak PVC casing can be used to hold the hole open and removed once testing is complete, at which point the open portion of the test nail is filled with a nonstructural filler and is abandoned if the nail is sacrificial or filled with the grout used for the bonded zone if the nail is a production (i.e., permanent) nail.

### 11.12.10—Drainage

The provisions of Article 3.11.3 shall apply.

Surface water runoff and groundwater shall be controlled both during and after construction of the soil

### C11.12.10

See Article C3.11.3. Also see FHWA-NHI-14-007/ FHWA GEC 7 (Lazarte et al. 2015) for further guidance about methods to control drainage behind soil nail walls.

nail wall. Soil nail walls shall contain sufficient drainage elements such that:

- No build-up of hydrostatic forces occurs between the wall facing and excavation face.
- Pore water pressures from perched water or groundwater do not negatively affect nail performance.

If perched groundwater or the groundwater table is anticipated to be above the base of the wall, horizontal or subhorizontal drains should be used to reduce the effect of pore pressure on the stability of the wall and any impacts on the long-term performance and durability of the nails. If horizontal drains are not practical to use, then the wall shall be designed for the long-term presence of ground water in the wall, considering both wall stability and the effect of long-term water exposure on the life of the soil nails and connection to the facing.

A concrete-lined diversion ditch should be located at the top of the wall to control surface water runoff toward the wall face to limit infiltration into the retained soil. A diversion ditch may not be necessary if the area above the wall slopes away from the wall face.

Vertical geocomposite strip drains installed behind the initial facing and adjacent to the excavation face should be used to prevent the build-up of hydrostatic pressures behind the wall facing due to incidental water and minor surface infiltration. The strip drains should be fitted with drainage elements at the bottom of the wall that allow exit of the water from the strips to the outside of the wall. Vertical strip drains should not be solely relied upon to provide complete reduction of hydrostatic pressure if perched water or elevated groundwater is present. Vertical strip drains are typically spaced at one to two times the horizontal spacing of the nails, $S_H$, with a spacing equal to $S_H$ being more common. Strip drain width and spacing are commonly selected based on judgment and experience; however, the designer should consider problems with sloughing of shotcrete if not enough soil face contact area is provided.

To design a drainage system consisting of drilled horizontal or subhorizontal drains, a seepage analysis should be performed to determine the diameter, length, and spacing of drilled horizontal drains. Typically, horizontal drains are installed horizontally or with mild upslope (5–10 degrees from horizontal).

# APPENDIX A11—SEISMIC DESIGN OF RETAINING STRUCTURES

## A11.1—GENERAL

This Appendix provides information that supplements the provisions contained in Section 11 regarding the design of walls and free-standing abutments for seismic loads. Detailed design methodology is provided for the calculation of seismic earth pressures, both active and passive. Design methodology is also provided for the estimation of deformation effects on the seismic acceleration a wall will experience.

## A11.2—PERFORMANCE OF WALLS IN PAST EARTHQUAKES

Even as early as 1970, Seed and Whitman (1970) concluded that "many walls adequately designed for static earth pressures will automatically have the capacity to withstand earthquake ground motions of substantial magnitudes and, in many cases, special seismic provisions may not be needed." Seed and Whitman further indicated that this statement applies to gravity and semigravity walls with peak ground accelerations up to 0.25g. More recently, Bray et al. (2010) and Lew et al. (2010a, 2010b) indicate that lateral earth pressure increases due to seismic ground motion are likely insignificant for peak ground accelerations of 0.3g to 0.4g or less, indicating that walls designed to resist static loads (i.e., the strength and service limit states) will likely have adequate stability for the seismic loading case, especially considering that load and resistance factors used for Extreme Event I limit state design are at or near 1.0.

Following the 1971 San Fernando earthquake, Clough and Fragaszy (1977) assessed damage to floodway structures, consisting of reinforced concrete cantilever (vertical) walls structurally tied to a floor slab forming a continuous U-shaped structure. They found that no damage was observed where peak ground accelerations along the structures were less than 0.5g. However, damage and wall collapse was observed where accelerations were higher than 0.5g, or localized damage occurred where the structures crossed the earthquake fault. They noted that while higher strength steel rebar was used in the actual structure than required by the static design, the structure was not explicitly designed to resist seismic loads. Gazetas et al. (2004) observed that cantilever semigravity walls with little or no soil surcharge exposed to shaking in the 1999 Athens earthquake performed well for peak ground accelerations up to just under 0.5g even though the walls were not specifically designed to handle seismic loads. Lew et al. (1995) made similar observations with regard to tied back shoring walls in the 1994 Northridge Earthquake and Tatsuoka (1996) similarly observed good wall performance for MSE type gravity walls in the 1995 Kobe earthquake. See Bray et al. (2010), Lew et al. (2010a, 2010b), and Al Atik and Sitar (2010) for additional background on observed wall performance and the generation of seismic earth pressures.

Walls meeting the requirements in Article 11.5.4.2 that allow a seismic analysis to not be conducted have demonstrated consistently good performance in past earthquakes. For wall performance in specific earthquakes, see the following:

- Gravity and semigravity cantilever walls in the 1971 San Fernando Earthquake (Clough and Fragaszy, 1977).
- Gravity and semigravity cantilever walls in the 1999 Athens Earthquake (Gazetas et al., 2004).
- Soil nail walls and MSE walls in the 1989 Loma Prieta, California earthquake (Vucetic et al., 1998 and Collin et al.,1992, respectively).
- MSE walls in the 1994 Northridge, California earthquake (Bathurst and Cai, 1995).
- MSE walls and reinforced concrete gravity walls in the 1995 Kobe, Japan earthquake (Tatsuoka et al., 1996).
- MSE walls and concrete gravity and semigravity walls in the 2010 Maule, Chile earthquake (Yen et al., 2011).
- Summary of the performance of various types of walls (Koseki et al., 2006).
- Reinforced earth walls withstand Northridge Earthquake (Frankenberger et al., 1996).
- The Performance of Reinforced Earth Structures in the Vicinity of Kobe during the Great Hanshin Earthquake (Kobayashi et al, 1996).
- Evaluation of Seismic Performance in Mechanically Stabilized Earth Structures (Sankey et al., 2001).

However, there have been some notable wall failures in past earthquakes. For example, Seed and Whitman (1970) indicated that some concrete gravity walls and quay walls (both gravity structures and anchored sheet pile nongravity cantilever walls), in the great Chilean Earthquake of 1960 and in the Niigata, Japan Earthquake of 1964, suffered severe displacements or even complete collapse. In most of those cases, significant liquefaction behind or beneath the wall was the likely cause of the failure. Hence, Article 11.5.4.2 specifies that a seismic analysis should be performed if liquefaction or severe strength loss in sensitive clays can cause instability of the wall. Seed and Whitman (1970) indicate, however, that collapse of walls located above the water table has been an infrequent occurrence.

Tatsuoka et al. (1996) indicated that several of the very old (1920s to 1960s) unreinforced masonry gravity walls and concrete gravity structures exposed to strong shaking in the 1995 Kobe Japan earthquake did collapse. In those

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

cases, collapse was likely due to the presence of weak foundation soils that had inadequate bearing and sliding resistance and, in a few cases, due to the presence of a very steep sloping surcharge (e.g., 1.5*H*:1*V*) combined with poor soil conditions. Soil liquefaction may have been a contributing factor in some of those cases. These wall collapses were mostly located in the most severely shaken areas (e.g., as high as 0.6g to 0.8g). As noted previously, Clough and Fragaszy (1977) observed concrete cantilever walls supporting open channel floodways that had collapsed where peak ground accelerations were 0.5g or more in the 1971 San Fernando earthquake. However, in that case, soil conditions were good. All of these wall cases where collapse or severe damage/deformations occurred are well outside of the conditions and situations where Article 11.5.4.2 allows the seismic design of walls to be waived.

Setting the limit at 0.4g for the Article 11.5.4.2 no seismic analysis provision represents a reasonable compromise between observations from laboratory modeling and full-scale wall situations (i.e., lab modeling indicates that seismic earth pressures are very low, below 0.4g, and walls in actual earthquakes start to have serious problems, including collapses even in relatively good soils, when the acceleration is greater than 0.5g and the wall has not been designed for the full seismic loading). However, if soil strength loss and flow due liquefaction or strength loss in sensitive silts and clays occurs, wall collapse can occur at lower acceleration values. Note that for the lab model studies, the 0.4g limit represents the limit at which significant seismic earth pressure does not appear to develop. However, for walls with a significant structural mass, the inertial force on the wall mass itself can still occur at accelerations less than 0.4g. At 0.4g, the combination of seismic earth pressure and wall inertial force is likely small enough still to not control the forces in the wall and its stability, provided the wall mass is not large. For typical gravity walls, the wall mass would not be large enough to offset the lack of seismically increased earth pressure below 0.4g. A possible exception regarding wall mass inertial forces is reinforced soil walls, though that inertial mass consists of soil within the reinforced soil zone. However, due to their flexibility, reinforced soil walls perform better than reinforced concrete walls, so the inertial mass issue may not be as important for that type of wall. Note that experience with walls in actual earthquakes in which the walls have not been designed for seismic loads is limited. So, while all indications are that major wall problems do not happen until the acceleration is greater than $A_s$ of 0.5g, the majority of those walls where such observations could be made have been strengthened to resist some degree of seismic loading. If walls are not designed for seismic loads, it is reasonable to back off a bit from the observed 0.5g threshold. Hence, 0.4g represents a reasonable buffer relative to potential severe wall damage or collapse as observed for walls in earthquakes at 0.5g or more.

Based on previous experience, walls that form tunnel portals have tended to exhibit more damage due to earthquakes than free-standing walls. It is likely that the presence of the tunnel restricts the ability of the portal wall to move, increasing the seismic forces to which the wall is subjected. Hence, a seismic design is recommended in such cases.

## A11.3—CALCULATION OF SEISMIC ACTIVE PRESSURE

Seismic active earth pressures have historically been estimated using the Mononobe–Okabe Method. However, this method is not applicable in some situations. More recently, Anderson et al. (2008) have suggested a generalized limit equilibrium (GLE) method that is more broadly applicable. Both methods are provided herein. Specifications which should be used to select which method to use are provided in Article 11.6.5.3.

### A11.3.1—Mononobe–Okabe Method

The method most frequently used for the calculation of the seismic soil forces acting on a bridge abutment or free-standing wall is a pseudostatic approach developed in the 1920s by Mononobe (1929) and Okabe (1926*)*. The Mononobe–Okabe analysis is an extension of the Coulomb sliding-wedge theory, taking into account horizontal and vertical inertia forces acting on the soil. The analysis is described in detail by Seed and Whitman (1970) and Richards and Elms (1979). The following assumptions are made:

1. The abutment is free to yield sufficiently to enable full soil strength or active pressure conditions to be mobilized. If the abutment is rigidly fixed and unable to move, the soil forces will be much higher than those predicted by the Mononobe–Okabe analysis.
2. The backfill is cohesionless, with a friction angle of $\phi$.
3. The backfill is unsaturated, so that liquefaction problems will not arise.

The M–O Method is illustrated in Figure A11.3.1-1 and the equation used to calculate $K_{AE}$ follows the figure.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

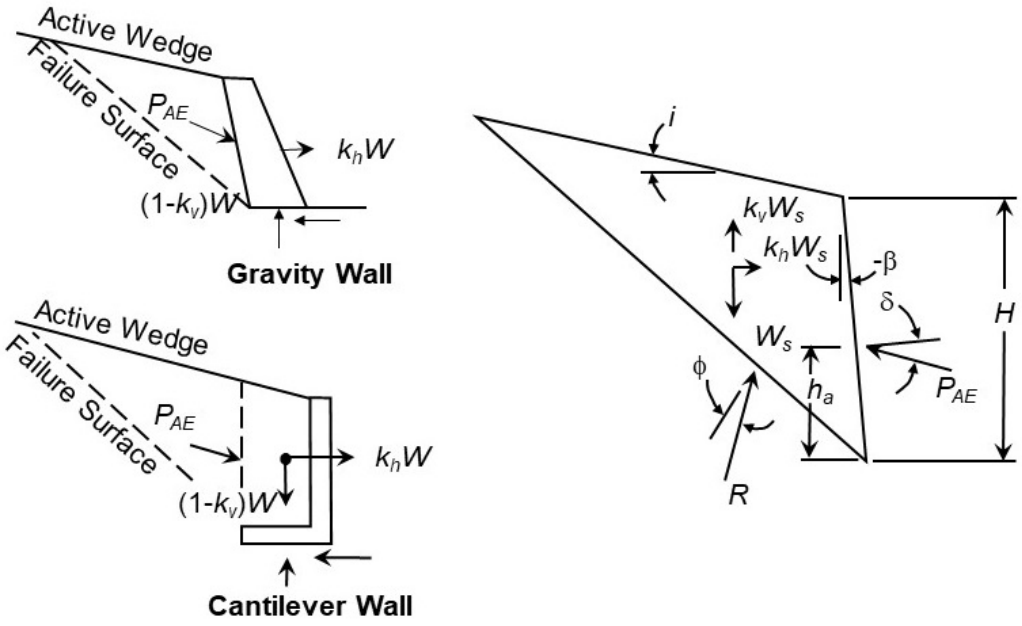

**Figure A11.3.1-1—Mononobe–Okabe Method Force Diagrams**

$$K_{AE} = \frac{\cos^2(\phi - \theta_{MO} - \beta)}{\cos\theta_{MO}\cos^2\beta\cos(\delta + \beta + \theta_{MO})} \times \left[1 + \sqrt{\frac{\sin(\phi + \delta)\sin(\phi - \theta_{MO} - i)}{\cos(\delta + \beta + \theta_{MO})\cos(i - \beta)}}\right]^{-2} \quad \text{(A11.3.1-1)}$$

where:

$K_{AE}$ = seismic active earth pressure coefficient (dim)
$\gamma$ = unit weight of soil (kcf)
$H$ = height of wall (ft)
$h$ = vertical distance between ground surface and wall base at the back of wall heel (ft)
$\phi_f$ = friction angle of soil (degrees)
$\theta_{MO}$ = arc tan $[k_h/(1 - k_v)]$ (degrees)
$\delta$ = wall backfill interface friction angle (degrees)
$k_h$ = horizontal seismic acceleration coefficient (dim.)
$k_v$ = vertical seismic acceleration coefficient (dim.)
$i$ = backfill slope angle (degrees)
$\beta$ = slope of wall to the vertical, negative as shown (degrees)

In discussion of the M–O Method to follow, $H$ and $h$ should be considered interchangeable, depending on the type of wall under consideration (see Figure A11.3.1-1).

Mononobe and Matsuo (1932) originally suggested that the resultant of the active earth pressure during seismic loading remain the same as for when only static forces are present (i.e., $H/3$ or $h/3$). However, theoretical considerations by Wood (1973), who found that the resultant of the dynamic pressure acted approximately at midheight and empirical considerations from model studies summarized by Seed and Whitman (1970) who suggested that $h_a$ could be obtained by assuming that the static component of the soil force acts at $H/3$ from the bottom of the wall and the additional dynamic effect acts at a height of $0.6H$, resulted in increasing the height of the resultant location above the wall base. Therefore, in past practice, designers have typically assumed that $h_a = H/2$ with a uniformly distributed pressure. Note that if the wall has a protruding heel or if the wall is an MSE wall, then replace $H$ with $h$ in the preceding discussion.

Back analysis of full-scale walls in earthquakes, however, indicates earth pressure resultants located higher than $h/3$ will overestimate the force, resulting in a prediction of wall failure when in reality the wall performed well (Clough and Fragaszy, 1977). Recent research indicates the location of the resultant of the total earth pressure (static plus seismic) should be located one-third up from the wall based on centrifuge model tests on gravity walls (Al Atik and Sitar, 2010;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Bray et al., 2010; and Lew et al., 2010). However, work by others (Nakamura, 2006) also indicates that the resultant location could be slightly higher, depending on the specifics of the ground motion and the wall details.

A reasonable approach is to assume that for routine walls, the combined static/seismic resultant should be located at the same location as static earth pressure resultant but no less than $h/3$. Because there is limited evidence that in some cases the combined static/seismic resultant location could be slightly higher than the static earth pressure resultant, a slightly higher resultant location (e.g., $0.4h$ to $0.5h$) for seismic design of walls for which the impact of wall failure is relatively high should be considered. However, for routine wall designs, a combined static/seismic resultant location equal to that used for static design (e.g., $h/3$) is sufficient.

The effects of abutment inertia are not taken into account in the Mononobe–Okabe analysis. Many current procedures assume that the inertia forces due to the mass of the abutment itself may be neglected in considering seismic behavior and seismic design. This is not a conservative assumption, and for those abutments relying on their mass for stability, it is also an unreasonable assumption in that to neglect the mass is to neglect a major aspect of their behavior. The effects of wall inertia are discussed further by Richards and Elms (1979), who show that wall inertia forces should not be neglected in the design of gravity-retaining walls.

**A11.3.2—Modification of Mononobe–Okabe Method to Consider Cohesion**

The M–O equation for seismic active earth pressure determination has many limitations, as discussed in Anderson et al. (2008). These limitations include the inability to account for cohesion that occurs in the soil. This limitation has been addressed by rederiving the seismic active earth pressure using a Coulomb-type wedge analysis. Generally, soils with more than 15 percent fines content can be assumed to be undrained during seismic loading. For this loading condition, total stress soil parameters, $\gamma$ and c, should be used.

Eq. A11.3.2-1 provided by Anderson et al. (2008), and Figure A11.3.2-1 shows the terms in the equation. This equation is very simple and practical for the design of the retaining walls and the equation has been calibrated with slope stability computer programs.

$$P_{AE} = \frac{W\left[(1-k_v)\tan(\alpha-\phi)+k_h\right]-C\,L\,\left[\sin\alpha\tan(\alpha-\phi)+\cos\alpha\right]-C_A\,H\left[\tan(\alpha-\phi)\cos\omega+\sin\omega\right]}{\left[1\;+\;\tan(\delta+\omega)\tan(\alpha-\phi)\right]*\cos(\delta+\omega)} \qquad \text{(A11.3.2-1)}$$

The only variables in Eq. A11.3.2-1 are the failure plane angle, $\alpha$, and the trial wedge surface length, $L$. Values of friction angle, $\phi$, seismic horizontal coefficient, $k_h$, seismic vertical coefficient, $k_v$, soil cohesion, $C$, soil wall adhesion, $C_a$, soil wall friction, $\delta$, and soil wall angle, $\omega$, are defined by the designer on the basis of the site conditions and the U.S. Geological Survey seismic hazard maps shown in Section 3.

The recommended approach in this Section is to assume that $k_v = 0$, and $k_h$ = the $PGA$ adjusted for site effects (i.e., $A_s$, $k_{h0,}$ or $k_h$, or some combination thereof, if the wall is greater than 20.0 ft in height and horizontal wall displacement can occur and is acceptable). A 50 percent reduction in the resulting seismic coefficient is used when defining $k_h$ if 1.0 to 2.0 in. of permanent ground deformation is permitted during the design seismic event. Otherwise, the peak ground acceleration coefficient should be used. Eq. A11.3.2-1 can be easily calculated in a spreadsheet. Using a simple spreadsheet, the user can search for the angle, $\alpha$, and calculate maximum value of $P_{AE}$.

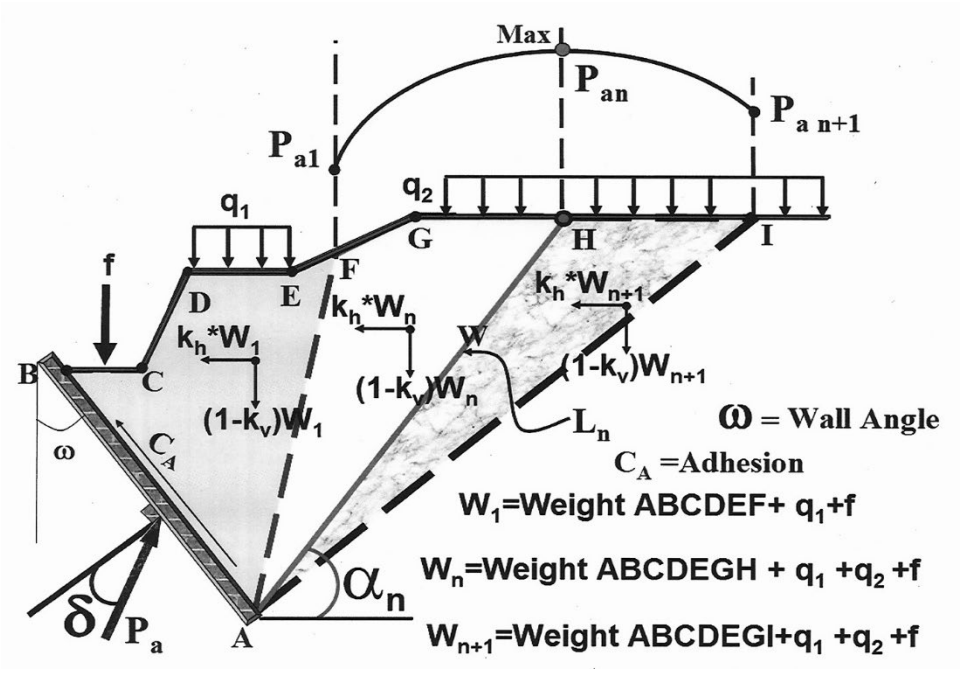

**Figure A11.3.2-1—Active Seismic Wedge**

The following charts were developed using Eq. A11.3.2-1. These charts are based on level ground behind the wall and a wall friction, δ, of 0.67ϕ. Generally, for active pressure determination, the wall interface friction has a minor effect on the seismic pressure coefficient. However, Eq. A11.3.2-1, the generalized limit equilibrium method, or the charts can be rederived for the specific interface wall friction if this effect is of concern or interest.

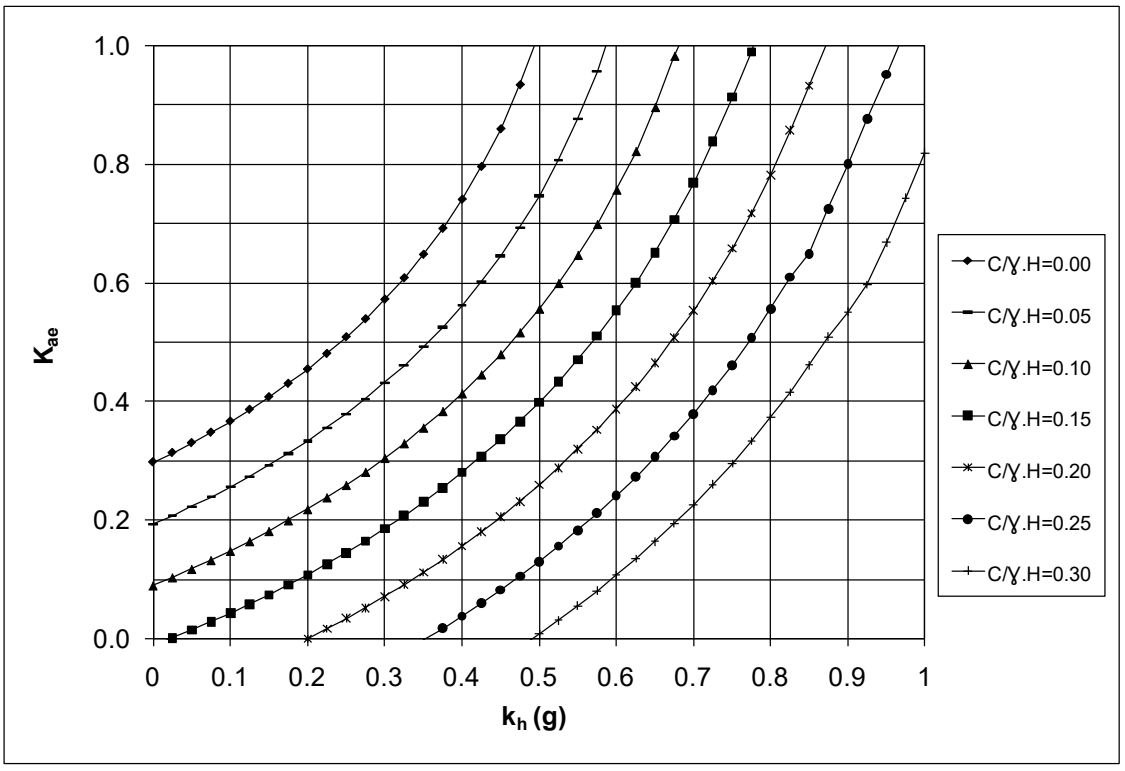

**Figure A11.3.2-2—Seismic Active Earth Pressure Coefficient for ϕ = 30 degrees (*c* = Soil Cohesion, γ = Soil Unit Weight, and *H* = Retaining Wall Height)**

Note: $k_h = A_s = k_{h0}$ for wall heights greater than 20.0 ft. This could be *H* or *h* as defined in Figure A11.3.1-1.

### A11.3.3—Generalized Limit Equilibrium (GLE) Method

In some situations, the M–O equation is not suitable due to the geometry of the backfill, the angle of the failure surface relative to the cut slope behind the wall, the magnitude of ground shaking, or some combination of these factors (see Article C11.6.5.3). In such situations, a generalized limit equilibrium (GLE) method involving the use of a computer program for slope stability is likely to be more suitable for determining the earth pressures required for retaining wall design.

Steps in GLE analysis are as follows:

- Set up the model geometry, groundwater profile, and design soil properties. The internal vertical face at the wall heel or the plane where the earth pressure needs to be calculated should be modeled as a free boundary.
- Choose an appropriate slope stability analysis method. Spencer's method generally yields good results because it satisfies the equilibrium of forces and moments.
- Choose an appropriate sliding surface search scheme. Circular, linear, multi-linear, or random surfaces can be examined in many commercial slope stability analysis programs.
- Apply the earth pressure as a boundary force on the face of the retained soil. For seismic cases, the location of the force may be initially assumed at $^1/_3H$) of the retained soil. However, different application points between $^1/_3H$ and $0.6H$ from the base may be examined to determine the maximum seismic earth pressure force. The angle of applied force depends on assumed friction angle between the wall and the fill soil (typically $2/3\phi_f$ for rigid gravity walls) or the fill friction angle (semigravity walls). If static (i.e., nonseismic) forces are also needed, the location of the static force is assumed at one-third from base ($^1/_3H$, where $H$ is retained soil height).
- Search for the load location and failure surface giving the maximum load for limiting equilibrium (capacity-to-demand ratio of 1.0, i.e., $FS = 1.0$).
- Verify design assumptions and material properties by examining the loads on individual slices in the output as needed.

Additional discussion and guidance regarding this approach is provided in NCHRP Report 611 (Anderson et al., 2008).

### A11.4—SEISMIC PASSIVE PRESSURE

This Article provides charts for determination of seismic passive earth pressures coefficients for a soil with both cohesion and friction based on the log spiral method. These charts were developed using a pseudostatic equilibrium method reported in Anderson et al. (2008). The method includes inertial forces within the soil mass, as well as variable soil surface geometries and loads.

Equations used in this approach are given below. Figure A11.4-1 defines the terms used in the equation.

$$dE_i = \frac{W_i(1-K_v)\left[\tan(\alpha_i+\phi)-K_h\right]+C\,L_i\,\left[\sin\alpha_i\,\tan(\alpha_i+\phi)+\cos\alpha_i\right]}{\left[1-\tan\delta_i\,\tan(\alpha_i-\phi)\right]*\cos\delta_i} \tag{A11.4-1}$$

$$P_Pn = \frac{\sum_1^i dE}{\left[1-\tan\delta_w\,\tan(\alpha_w-\phi)\right]*\cos\delta_w} \tag{A11.4-2}$$

$$K_Pn = \frac{2P_P}{\gamma\,h^2} \tag{A11.4-3}$$

where $\phi$ is the soil friction angle, $c$ is the cohesion, and $\delta$ is wall interface friction.

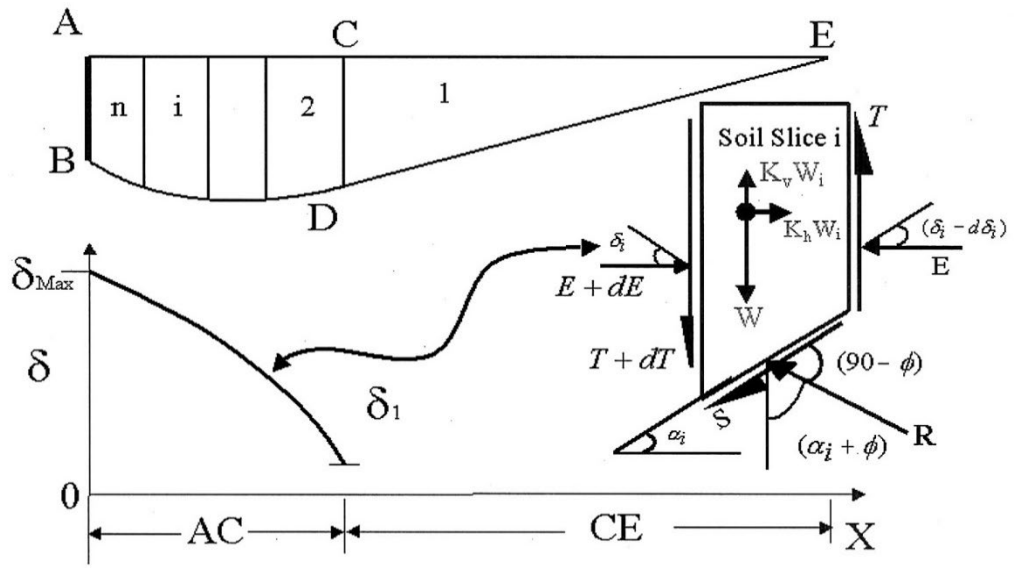

**Figure A11.4-1—Limits and Shape Seismic Interslice Force Function (reported in Anderson et al., 2008)**

As shown, the method of analysis divides the sliding mass of the backfill into many slices. It is assumed that the shear forces dissipate from a maximum at the wall face (*AB*) to the induced seismic shear forces at the face (*CD*) of the first slice as seen in Figure A11.4-1.

The methodology described above was used to develop a series of charts (Figures A11.4-2 through A11.4-4) for a level backfill condition. These charts can be used to estimate the seismic passive pressure coefficient. The interface friction for these charts is 0.67ϕ. These procedures and charts can be used to estimate the seismic passive coefficient for other interface conditions and soil geometries.

## A11.5—ESTIMATING WALL SEISMIC ACCELERATION CONSIDERING WAVE SCATTERING AND WALL DISPLACEMENT

The seismic acceleration acting on a wall during an earthquake is affected by both wave scattering and wall displacement (see Articles 11.6.5.2 and C11.6.5.2).

With regard to the effects of wall deformation during shaking, the Newmark sliding block concept (Newmark, 1965) was originally developed to evaluate seismic slope stability in terms of earthquake-induced slope displacement as opposed to a factor of safety against yield under peak slope accelerations. The concept is illustrated in Figure A11.5-1, where a double integration procedure on accelerations exceeding the yield acceleration of the slope leads to an accumulated downslope displacement.

The concept of allowing gravity walls to slide during earthquake loading and displacement-based design (i.e., using a Newmark sliding block analysis to compute displacements when accelerations exceed the horizontal limit equilibrium yield acceleration for the wall–backfill system) was introduced by Richards and Elms (1979). Based on this concept, Elms and Martin (1979) suggested that a design acceleration coefficient of 0.5 would be adequate for limit equilibrium pseudostatic design, provided allowance be made for a horizontal wall displacement of 10 *PGA* in inches. The *PGA* term in Elms and Martin is equivalent to the $F_{PGA}\ PGA$ or $k_{h0}$ in these Specifications.

For many situations, Newmark analysis or simplifications of it (e.g., displacement design charts or equations based on the Newmark analysis method for certain typical cases, or the use of $k_h = 0.5k_{h0}$) are sufficiently accurate. However, as the complexity of the site or the wall–soil system increases, more rigorous numerical modeling methods may become necessary.

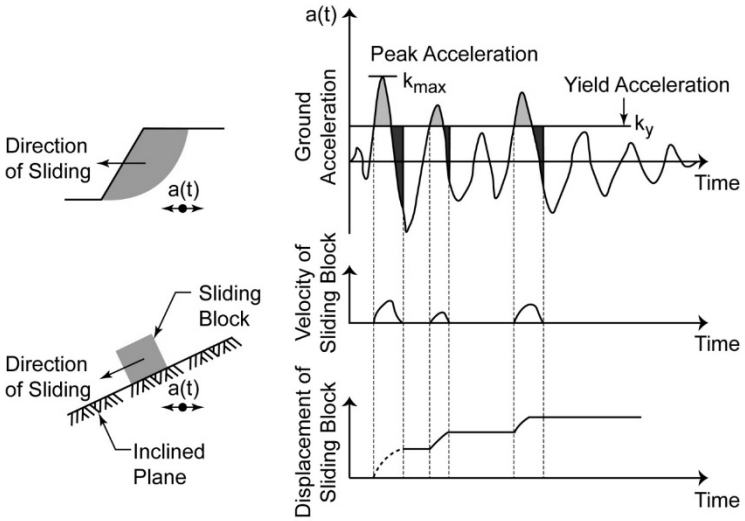

**Figure A11.5-1—Newmark Sliding Block Concept (after Anderson, et al. 2008)**

To assess the effects of wave scattering and lateral deformation on the design acceleration coefficient, $k_h$, three simplified design procedures to estimate the acceleration coefficient are provided in detail in the subarticles that follow. The first method (Kavazanjian et al., 1997) does not directly address wave scattering and, since wave scattering tends to reduce the acceleration, the first method is likely conservative. The second and third methods account for both wave scattering and wall deformation but are considerably more complex than the first method. With regard to estimation of wave scattering effects, the second method (Anderson et al., 2008) uses a simplified model that considers the effect of the soil mass, but not specifically the effect of the wall as a structure, whereas the third method (Bray et al., 2010) provides a simplified response spectra for the wall, considering the wall to be a structure with a fundamental period. With regard to the effect of lateral wall deformation on the wall acceleration, both methods are based on many Newmark analyses, using those analyses to develop empirical relationships between the yield acceleration for the wall and the soil it retains and the amount of deformation that occurs. The Anderson et al. (2008) method estimates the wall deformation for input yield acceleration, peak ground acceleration, and peak ground velocity, whereas the third method (Bray et al., 2010) estimates the reduced acceleration, $k_h$, for a specified deformation and spectral acceleration at a specified period. The three alternative design procedures should not be mixed together in any way.

### A11.5.1—Kavazanjian et al. (1997)

Kavazanjian et al. (1997) provided the following simplified relationship based on Newmark sliding analysis, assuming that the velocity, in the absence of information on the time history of the ground motion, is equal to 30$A$:

$$k_h = 0.74\, A_S \left(\frac{A_S}{d}\right)^{0.25} \tag{A11.5.1-1}$$

where:

$A_S$ = earthquake ground acceleration coefficient as specified in Eq. 3.10.4.2-2 (dim.)
$k_h$ = horizontal seismic acceleration coefficient (dim.)
$d$ = lateral wall displacement (in.)

This equation should not be used for displacements of less than 1.0 in. or greater than approximately 8 in., as this equation is an approximation of a more rigorous Newmark analysis. However, the amount of deformation which is tolerable will depend on the nature of the wall and what it supports, as well as what is in front of the wall. This method may be more conservative than the more complex methods that follow. Note that this method does not address wave scattering within the wall, which in most cases will be conservative.

### A11.5.2—NCHRP Report 611—Anderson et al. (2008)

For values of $h$ (as defined in Article 11.6.5.2.2) greater than 20.0 ft but less than 60.0 ft, the seismic coefficient used to compute lateral loads acting on a freestanding retaining wall may be modified to account for the effects of spatially varying ground motions behind the wall, using the following equation:

$$k_h = \alpha k_{h0} \tag{A11.5.2-1}$$

where:

$K_{h0}$ = $\alpha k_{h0}$
$\alpha$ = wall height acceleration reduction factor to account for wave scattering

For Site Class C, D, and E:

$$\alpha = 1 + 0.01h\left(0.5\beta - 1\right) \tag{A11.5.2-2}$$

where:

$h$ = vertical distance between ground surface and wall base at the back of wall heel (ft)
$\beta$ = $F_v S_1 / k_{h0}$
$S_1$ = spectral acceleration coefficient at 1 sec
$F_v$ = site class adjustment factor

For Site Classes A and B (hard and soft rock foundation soils), note that $k_{h0}$ is increased by a factor of 1.2 as specified in Article 11.6.5.2.1. Eq. A11.5.2-1 provides the value of $k_h$ if only wave scattering is considered and not lateral wall displacement.

For wall heights greater than 60.0 ft, special seismic design studies involving the use of dynamic numerical models should be conducted. These special studies are required in view of the potential consequences of failure of these very tall walls, as well as limitations in the simplified wave scattering methodology.

The basis for the height-dependent reduction factor described above is related to the response of the soil mass behind the retaining wall. Common practice in selecting the seismic coefficient for retaining wall design has been to assume rigid body soil response in the backfill behind a retaining wall. In this approach the horizontal seismic coefficient, $k_{h0}$, is assumed equal to the $F_{PGA}PGA$ when evaluating lateral forces acting on an active pressure failure zone. Whereas this assumption may be reasonable for wall heights less than about 20.0 ft, for higher walls, the magnitude of accelerations in soils behind the wall will vary spatially as shown schematically in Figure A11.5.2-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The nature and variation of the ground motions within a wall is complex and could be influenced by the dynamic response of the wall–soil system to the input earthquake ground motions. In addition to wall height, the acceleration distribution will depend on factors such as the frequency characteristics of the input ground motions, the stiffness contrast between backfill and foundation soils, the overall stiffness and damping characteristics of the wall, and wall slope. From a design standpoint, the net effect of the spatially varying ground motions can be represented by an averaging process over a potential active pressure zone, leading to a time history of average acceleration and hence a maximum average acceleration or seismic coefficient as shown in Figure A11.5.2-1.

To evaluate this averaging process, the results of a series of analytical studies are documented in NCHRP Report 611 (Anderson et al., 2008). An evaluation of these results forms the basis for the simplified Eqs. A11.5.2-1 and A11.5.2-2. The analytical studies included wave scattering analyses assuming elastic soil media using different slope heights, with slopes ranging from near vertical for short walls to significantly battered for tall walls, as well as slopes more typical of embankments ($3H$:$1V$) and with a range of earthquake time histories. The properties of the continuum used for these analyses were uniform throughout and therefore did not consider the potential effect of impedance contrasts between different materials (i.e., the properties of the wall vs. that of the surrounding soil). The acceleration time histories simulated spectral shapes representative of Western United States (WUS) and Central and Eastern United States (CEUS) sites and reflected different earthquake magnitudes and site conditions.

Additional height-dependent, one-dimensional SHAKE (Schnaebel et al., 1972) analyses were also conducted to evaluate the influence of nonlinear soil behavior and stiffness contrasts between backfill and foundation soils. These studies were also calibrated against finite element studies for MSE walls documented by Segrestin and Bastick (1988), which form the basis for the average maximum acceleration equation (a function of $A_s$) given in previous editions of these Specifications prior to the 7th. The results of these studies demonstrate that the ratio of the maximum average seismic coefficient, $k_h$, to $A_s$ (the α factor) is primarily dependent on the wall or slope height and the shape of the acceleration spectra (the β factor). The acceleration level has a lesser effect.

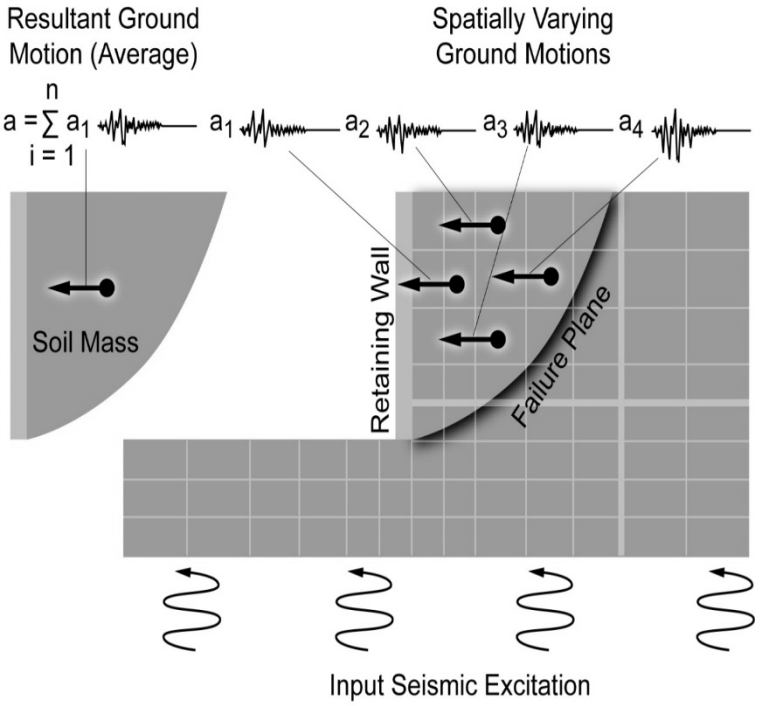

**Figure A11.5.2-1—Average Seismic Coefficient Concept (after Anderson, et al. 2008)**

Sliding block displacement analyses were conducted as part of NCHRP Report 611 (Anderson et al., 2008) using an extensive database of earthquake records. The objective of these analyses was to establish updated relationships between wall displacement, $d$, and the following three terms: the ratio $k_y/k_{h0}$, $k_{h0}$ as determined in Article 11.6.5.2.1, and $PGV$. Two broad groups of ground motions were used to develop these equations, CEUS and WUS, as shown in Figure A11.5.2-2 (Anderson et al., 2008). Regressions of those analyses result in the following equations that can be used to estimate the relationship between wall displacement and acceleration.

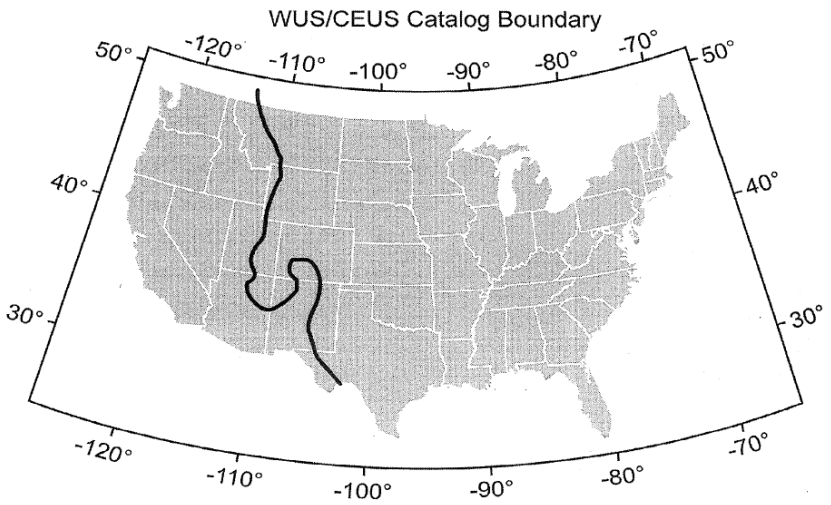

**Figure A11.5.2-2—Boundary between WUS and CEUS Ground Motions**

For all sites except CEUS rock sites (Categories A and B), the mean displacement (in.) for a given yield acceleration may be estimated as:

$$\log d = -1.51 - 0.74\log\left(\frac{k_y}{k_{h0}}\right) + 3.27\log\left(\frac{1-k_y}{k_{h0}}\right) - 0.80\log k_{h0} + 1.59\log\left(PGV\right) \quad \text{(A11.5.2-3)}$$

where:

$k_y$ = yield acceleration

For CEUS rock sites (Categories A and B), this mean displacement (in.) may be estimated as:

$$\log d = -1.31 - 0.93\log\left(\frac{k_y}{k_{h0}}\right) + 4.52\log\left(1-\frac{k_y}{k_{h0}}\right) - 0.46\log\left(k_{h0}\right) + 1.12\log\left(PGV\right) \quad \text{(A11.5.2-4)}$$

Note that the above displacement equations represent mean values.

In Eqs. A11.5.2-3 and A11.5.2-4, it is necessary to estimate the peak ground velocity, *PGV*, and the yield acceleration, $k_y$. Values of *PGV* may be determined using the following correlation between *PGV* and spectral ordinates at 1 sec ($S_1$).

$$PGV \text{ (in./sec)} = 38F_vS_1 \quad \text{(A11.5.2-5)}$$

where $S_1$ is the spectral acceleration coefficient at 1 sec and $F_v$ is the site class adjustment factor.

The development of the *PGV*-$S_1$ correlation is based on a simplification of regression analyses conducted on an extensive earthquake database established from recorded and synthetic accelerograms representative of both rock and soil conditions for WUS and CEUS. The study is described in NCHRP Report 611 (Anderson et al., 2008). It was found that earthquake magnitude need not be explicitly included in the correlation, as its influence on *PGV* is captured by its influence on the value of $S_1$. The equation is based on the mean from the simplification of the regression analysis.

Values of the yield acceleration, $k_y$, can be established by computing the seismic coefficient for global stability that results in a capacity-to-demand (*C*/*D*) ratio of 1.0 (i.e., for overall stability of the wall/slope, *FS* = 1.0). A conventional slope stability program is normally used to determine the yield acceleration. For these analyses, the total stress (undrained) strength parameters of the soil should usually be used in the stability analysis. See guidance on the use of soil cohesion for seismic analyses discussed in Article 11.6.5.3 and its commentary.

Once $k_y$ is determined, the combined effect of wave scattering and lateral wall displacement, *d,* on $k_h$ is determined as follows:

$$k_h = \alpha k_y \quad \text{(A11.5.2-6)}$$

### A11.5.3—Bray et al. (2010), and Bray and Travasarou (2009)

The Bray et al. (2010) method (see also Bray and Travasarou, 2009) for estimating the value of $k_h$ applied to the wall mass considers both the wave scattering and lateral deformation of the wall. The method was developed using 688 ground motion records. The method characterizes the ground motion using a spectral acceleration at five percent damping, the moment magnitude, $M$, as a proxy for duration of shaking, the fundamental period of the wall, $T_s$, and the lateral wall deformation allowed during shaking. In this method, $k_h$ is determined as follows:

$$k_h = \exp\left(\frac{-a+\sqrt{b}}{0.66}\right) \tag{A11.5.3-1}$$

where:

$a$ = $2.83 - 0.566ln(S_a)$
$b$ = $a^2 - 1.33[ln(d) + 1.10 - 3.04ln(S_a) + 0.244(ln(S_a))^2 - 1.5T_s - 0.278(M - 7) - \varepsilon]$
$S_a$ = the five percent damped spectral acceleration coefficient from the site response spectra
$d$ = the maximum wall displacement allowed, in centimeters
$M$ = the moment magnitude of the design earthquake
$T_s$ = the fundamental period of the wall
$\varepsilon$ = a normally distributed random variable with zero mean and a standard deviation of 0.66.

$\varepsilon$ should be set equal to zero to estimate $k_h$ considering $D_a$ to be a mean displacement. To calculate the fundamental period of the wall, $T_s$, use the following equation:

$$T_s = 4H'/V_s \tag{A11.5.3-2}$$

where:

$H'$ = 80 percent of the height of the wall, as measured from the bottom of the heel of the wall to the ground surface directly above the wall heel (or the total wall height at the back of the reinforced soil zone for MSE walls) (ft)
$V_s$ = the shear wave velocity of the soil behind the wall (ft/sec)

Note that $V_s$ and $H'$ must have consistent units. Shear wave velocities may be obtained from in-situ measurements or through the use of correlations to the Standard Penetration Resistance, *SPT*, or cone resistance, $q_c$. An example of this type of correlation for granular wall backfill materials is shown in Eq. A11.5.3-3 (Imai and Tonouchi, 1982).

$$V_s = 351N^{0.314} \tag{A11.5.3-3}$$

where:

$N$ = the Standard Penetration Resistance, *SPT*, of the fill material, uncorrected for overburden pressure but corrected for hammer efficiency

The spectral acceleration, $S_a$, is determined at a degraded period of $1.5T_s$ from the five percent damped response spectra for the site (i.e., either the response spectra determined using the general procedure or using a site-specific response spectra).

To estimate lateral wall displacement for a given acceleration value, see Bray et al. (2010) and Bray and Travasarou (2009) for details.

# APPENDIX B11—DETERMINATION OF $T_{MAX}$ FOR MSE WALLS USING THE SIMPLIFIED METHOD

## B11.1—GENERAL

This Appendix provides the procedures and requirements to determine the MSE wall reinforcement layer load, $T_{max}$, using the Simplified Method. Development of the Simplified Method is described in Allen et al. (2001).

## B11.2—DETERMINATION OF $T_{MAX}$

For the Simplified Method, the load in the reinforcements shall be obtained by multiplying the vertical earth pressure at the reinforcement layer level by an empirically adjusted lateral earth pressure coefficient, and applying the resulting lateral pressure to the tributary layer thickness for the reinforcement to estimate the reinforcement load, $T_{max}$. The vertical earth pressure at each reinforcement layer level shall be the sum of the soil self-weight plus any surcharge present.

The reinforcement load, $T_{max}$, at each reinforcement level shall be determined as:

$$T_{\max} = S_v k_r \left(\gamma_r Z + \gamma_f S\right) \quad \text{(B11.2-1)}$$

where:

$S_v$ = tributary vertical thickness for reinforcement layer as specified in Article 11.10.6.2.1b (ft)
$k_r$ = horizontal pressure coefficient of reinforced fill determined using Figure B11.2-1 (dim.)
$Z$ = depth of reinforcement layer below wall top (ft)
$\gamma_r$ = unit weight of soil in wall reinforcement zone (lbs/ft$^3$)
$S$ = average soil surcharge thickness over reinforcement within 0.7$H$ of the wall face (ft)
$\gamma_f$ = unit weight of soil in wall in surcharge above wall (lbs/ft$^3$)

Vertical stress for maximum reinforcement load calculations shall be determined as shown in Figures 11.10.6.2.1a-1 and 11.10.6.2.1a-2. Live load is not included in the vertical stress calculation to determine $T_{max}$ for assessing pullout loads when using the Simplified Method.

For design, the load factor applied to $T_{max}$ for the strength limit state, $\gamma_{p\text{-}EV}$, shall be 1.35 as specified in Table 3.4.1-2, and for other loads shall be as specified in Article 3.4.1. Resistance factors for design of steel reinforced MSE walls shall be as specified in Articles 11.5.7 and 11.5.8. For geosynthetic walls, the resistance factor for both pullout and tensile resistance for the strength limit state shall be 0.9. For the Extreme Event I limit state (i.e., seismic), the resistance factor for geosynthetic reinforcement tensile and pullout resistance shall be 1.2.

$k_a$ shall be determined as specified in Articles 11.10.6.2.1c and C11.10.6.2.1c, specifically Eqs. C11.10.6.2.1c-1 and C11.10.6.2.1c-2. The horizontal pressure coefficient, $k_r$, is determined by applying a multiplier to the active earth pressure coefficient, $k_a$. The $k_a$ multiplier for the Simplified Method shall be determined as shown in Figure B11.2-1. For assessment of reinforcement pullout, the Simplified Method multiplier for steel strip walls shall be used for all steel reinforced walls. For reinforcement rupture, the multiplier applicable to the specific type of steel reinforcement shall be used. Based on Figure B11.2-1, the $k_a$ multiplier is a function of the reinforcement type and the depth of the reinforcement below the wall top.

Since the lateral stress ratios in this figure have been empirically derived, these values should not be used for wall design cases that are beyond their empirical basis. For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

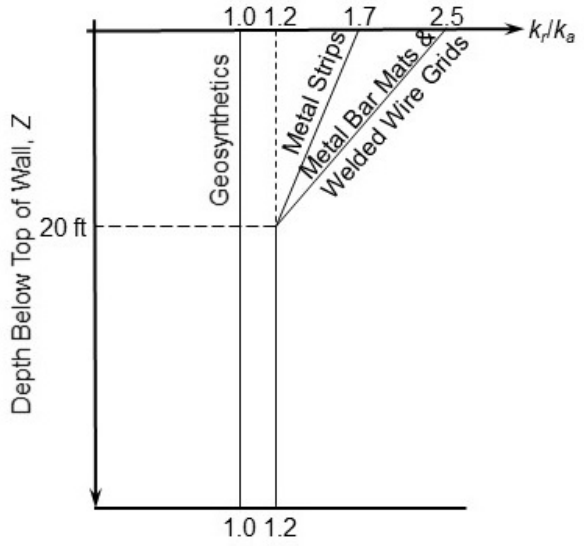

**Figure B11.2-1—Variation of the Coefficient of Lateral Stress Ratio, $k_r/k_a$, with Depth in a Mechanically-Stabilized Earth Wall**

The reinforcement shall be designed for pullout, and reinforcement and connection rupture as specified in Articles 11.10.6.3 and 11.10.6.4, respectively. If live load is present, due to the difference in load factors for soil self-weight and live load, $\gamma_{p\text{-}EV}T_{max}$ in Eqs. 11.10.6.3.2-1 and 11.10.6.4.1-1 shall be replaced with $T_{totalf}$ calculated as follows when using the Simplified Method:

$$T_{totalf} = \gamma_{p-EV}T_{\max} + \gamma_{LS}S_v k_r \gamma_f h_{eq} < \phi T_{a\ell}R_c \tag{B11.2-2}$$

where:

$T_{totalf}$ = total factored load for each reinforcement layer (lbs/ft)
$T_{max}$ = applied load to the reinforcement determined using Eq. B11.2-1 (kips/ft)
$\gamma_{p\text{-}EV}$ = load factor for vertical earth pressure specified in Table 3.4.1-2 (dim.)
$\phi$ = resistance factor for reinforcement tension, specified in Table 11.5.7-1 (dim.)
$T_{a\ell}$ = nominal long-term reinforcement strength (kips/ft)
$R_c$ = reinforcement coverage ratio specified in Article 11.10.6.4.1 (dim.)
$\gamma_{LS}$ = load factor for live load surcharge, *LS* (dim.)
$\gamma_f$ = unit weight of soil used to calculate live load surcharge, *LS* (lbs/ft$^3$)
$h_{eq}$ = equivalent height of soil for live load surcharge, as specified in Article 3.11.6.4 (ft)

Similarly, at the facing connection, $\gamma_{p\text{-}EV}T_o$ shall be replaced with $T_{totalfo}$ calculated as follows when using the Simplified Method:

$$T_{totalfo} = \gamma_{p-EV}T_o + (\gamma_{LS})\gamma_f h_{eq} < \phi T_{ac}R_c \tag{B11.2-3}$$

where:

$T_o$ = applied load at reinforcement/facing connection specified in Article 11.10.6.2.2 (kips/ft)

For more complex loading situations, such as due to the presence of concentrated loads due to foundations located on top of or within the reinforced soil and traffic barrier impact forces, replace $T_{max}$ and $T_o$ with $T_{totalf}$ and $T_{totalfo}$, respectively, as specified in Article 11.10.10, using $k_r$ determined from Figure B11.2-1.

SECTION 12

# BURIED STRUCTURES AND TUNNEL LINERS

## 12.1—SCOPE

This Section provides requirements for the selection of structural properties and dimensions of buried structures, e.g., culverts, and steel plate used to support tunnel excavations in soil.

Buried structure systems considered herein are metal pipe, structural plate pipe, long-span structural plate, deep corrugated plate, structural plate box, reinforced concrete pipe, reinforced concrete cast-in-place and precast arch, box and elliptical structures, thermoplastic pipe, and fiberglass pipe.

The type of liner plate considered is cold-formed steel panels.

## C12.1

For buried structures, refer to Article 2.6.6 and the *AASHTO Drainage Manual* (2014) for hydraulic design considerations and for design methods related to location, length, and waterway openings.

Thermoplastic and fiberglass pipe are flexible plastic pipes that have similarities in installation and design; however, not all thermoplastic pipe design and installation specifications are applicable to fiberglass pipe. Fiberglass pipe is a smooth-walled thermoset resin pipe that relies on composite glass fiber within its wall for strength; thermoplastic pipe can have either solid or profile walls of homogenous material. The design specifications for fiberglass pipe are contained in Article 12.15 with reference to applicable sections from the thermoplastic pipe design specifications. Construction specifications for fiberglass pipe are included in the *AASHTO LRFD Bridge Construction Specifications*, Section 30, "Thermoplastic Pipe," with the provisions for thermoplastic pipe applicable to fiberglass pipe installations except as noted.

## 12.2—DEFINITIONS

*Abrasion*—Loss of section or coating of a culvert by the mechanical action of water conveying suspended bed load of sand, gravel, and cobble-size particles at high velocities with appreciable turbulence.

*Buried Structure*—A generic term for a structure built by embankment or trench methods.

*Corrosion*—Loss of section or coating of a buried structure by chemical and/or electrochemical processes.

*Culvert*—A curved or rectangular buried conduit for conveyance of water, vehicles, utilities, or pedestrians.

*Culvert Material Service Life*—The time duration for a material that can satisfy the structural loading, hydraulic loading, and joint performance for the culvert service life duration.

*Culvert Service Life*—The time duration during which a culvert is expected to provide the desired function with a specified level of maintenance established at the design or retrofit stage.

*Deep Corrugated Plate*—Structural Plate in AASHTO M 167M/M 167 with a corrugation depth greater than 5.0 in.

*FEM*—Finite Element Method.

*Narrow Trench Width*—The outside span of rigid pipe, plus 1.0 ft.

*Projection Ratio*—Ratio of the vertical distance between the outside top of the pipe and the ground or bedding surface to the outside vertical height of the pipe, applicable to reinforced concrete pipe only.

*Side Radius*—For deep corrugated plate structures, the side radius is the radius of the plate in the section adjacent to crown (top) section of the structure. In box-shaped structures, this is often called the haunch radius.

*Soil Envelope*—Zone of controlled soil backfill around culvert structure required to ensure anticipated performance based on soil–structure interaction considerations.

*Soil–Structure Interaction System*—A buried structure whose structural behavior is influenced by interaction with the soil envelope.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*Tunnel*—A horizontal or near horizontal opening in soil excavated to a predesigned geometry by tunneling methods exclusive of cut-and-cover methods.

## 12.3—NOTATION

$A$ = wall area (in.$^2$/ft) (12.7.2.3)
$A_{eff}$ = effective wall area (in.$^2$/in.) (12.12.3.10.1b)
$A_g$ = gross wall area within a length of one period (in.$^2$/in.); area of fiber-reinforced pipe wall per unit length of pipe (12.12.3.5) (12.15.6.3) (12.12.3.10.1b)
$A_L$ = axle load, taken as 50 percent of all axle loads that can be placed on the structure at one time (kip); sum of all axle loads in an axle group (kip); total axle load on single axle or tandem axles (kip) (12.8.4.2) (12.9.4.2) (12.9.4.5)
$A_s$ = tension reinforcement area on cross-section width, $b$ (in.$^2$/ft) (12.10.4.2.4a) (12.10.4.2.4b) (C12.11.4)
$A_{smax}$ = minimum flexural reinforcement area without stirrups (in.$^2$/ft) (12.10.4.2.4c)
$A_T$ = area of the top portion of the structure above the springline (ft$^2$) (12.8.4.2)
$A_{vr}$ = stirrup reinforcement area to resist radial tension forces on cross-section width, $b$, in each line of stirrups at circumferential spacing, $s_v$ (in.$^2$/ft) (12.10.4.2.6)
$A_{vs}$ = required area of stirrups for shear reinforcement (in.$^2$/ft) (12.10.4.2.6)
$B$ = width of culvert (ft) (C12.6.2.2.5) (12.11.2.2.1)
$B_c$ = outside diameter or width of the structure (ft) (12.6.6.3) (12.11.2.2.1)
$B'_c$ = out-to-out vertical rise of pipe (ft) (12.6.6.3)
$B_d$ = horizontal width of trench at top of pipe (ft) (12.11.2.2)
$B_{FE}$ = earth load bedding factor (12.10.4.3.1)
$B_{FLL}$ = live load bedding factor (12.10.4.3.1)
$B_1$ = crack control coefficient for effect of cover and spacing of reinforcement (C12.10.4.2.4d)
$b$ = width of section (12.10.4.2.4c) (12.10.4.2.4a)
$b_e$ = element effective width (in.) (12.12.3.10.1b)
$C_A$ = constant corresponding to the shape of the pipe (12.10.4.3.2a)
$C_c$ = load coefficient for positive pipe projection (12.10.4.3.2a)
$C_d$ = load coefficient for trench installation (12.11.2.2)
$C_{dt}$ = load coefficient for tunnel installation (12.13.2.1)
$C_H$ = adjustment factor for shallow cover heights over metal box culverts (12.9.4.4)
$C_L$ = width of culvert on which live load is applied parallel to span (ft); live load coefficient as specified in Article 12.12.3.5 (12.7.2.2) (12.12.2.2)
$C_n$ = calibration factor to account for nonlinear effects (12.12.3.10.1e)
$C_{\ell\ell}$ = live load adjusted for axle loads, tandem axles, and axles with other than four wheels; $C_1\,C_2\,A_L$ (kip) (12.9.4.2)
$C_N$ = parameter that is a function of the vertical load and vertical reaction (12.10.4.3.2a)
$C_n$ = scalar calibration factor to account for some nonlinear effects (12.8.9.6)
$C_S$ = steel tunnel liner plate construction stiffness (12.13.3.5)
$C_s$ = construction stiffness for tunnel liner plate (kip/in.) (12.5.6.4)
$C_1$ = 1.0 for single axles and $0.5 + S/50 \le 1.0$ for tandem axles; adjustment coefficient for number of axles; crack control coefficient for various types of reinforcement (12.9.4.2) (12.9.4.3) (C12.10.4.2.4d)
$C_2$ = adjustment factor for number of wheels on a design axle as specified in Table 12.9.4.2-1; adjustment coefficient for number of wheels per axle (12.9.4.2) (12.9.4.3)
$c$ = the larger of the distance from neutral axis of profile to the extreme innermost or outermost fiber (in.) (12.12.3.10.2b)
$D$ = straight leg length of haunch (in.); pipe diameter (in.); required D-load capacity of reinforced concrete pipe (klf); diameter to centroid of pipe wall (in.) (C12.6.7) (12.9.4.1) (12.12.2.2)
*D-load* = resistance of pipe from three-edge bearing test load to produce a 0.01-in. crack (klf) (12.10.4.3.1)
$D_f$ = shape factor (12.12.3.10.2b)
$D_L$ = deflection lag factor (12.12.2.2)
$D_o$ = outside diameter of pipe (in.) (12.12.2.2) (12.7.2.2) (12.10.2.1) (12.15.2)
$d$ = required envelope width adjacent to the structure (ft); distance from compression face to centroid of tension reinforcement (in.) (12.8.5.3) (12.10.4.2.4a) (C12.11.4)
$d'$ = width of warped embankment fill to provide adequate support for skewed installation (ft) (C12.6.8.2)
$d_1$ = distance from the structure (ft) (12.8.5.3)
$E$ = modulus of elasticity of the plastic (ksi); initial modulus of elasticity (ksi) (12.12.3.3) (12.12.3.6)
$E_{cf}$ = circumferential flexural modulus (ksi) (12.15.5.2) (12.15.3.1)
$E_m$ = modulus of elasticity of metal (ksi) (12.7.2.4)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$E_p$ = short- or long-term modulus of pipe material as specified in Table 12.12.3.3-1 (ksi) (12.12.2.2) (12.8.9.6)
$E(x)$ = lateral unbalanced distributed load on culvert below sloping ground and skewed at end wall (lbs.) (C12.6.2.2.5)
$F$ = concentrated load acting at the crown of a culvert (kip) (C12.6.2.2.5)
$F_c$ = curvature correction factor (12.10.4.2.5)
$F_{cr}$ = factor for adjusting crack control relative to average maximum crack width of 0.01 in. corresponding to $F_{cr} = 1.0$ (12.10.4.2.4d)
$F_d$ = factor for crack depth effect resulting in increase in diagonal tension, shear, and strength with decreasing $d$ (12.10.4.2.5)
$F_e$ = soil–structure interaction factor for embankment installations (12.10.2.1)
$FF$ = flexibility factor (in./kip) (12.5.6.3) (12.7.2.6)
$F_n$ = coefficient for effect of thrust on shear strength (12.10.4.2.5)
$F_{rp}$ = factor for process and local materials affecting radial tension strength of pipe (12.10.4.2.3)
$F_{rt}$ = factor for pipe size effect on radial tension strength (12.10.4.2.4c)
$F_t$ = soil–structure interaction factor for trench installations (12.11.2.2.1)
$F_u$ = specified minimum tensile strength (ksi); material yield strength for design load duration (ksi) (12.7.2.4) (12.12.3.10.1b)
$F_{vp}$ = process and material factors for shear strength for design of plant-made reinforced concrete pipe (12.10.4.2.3)
$F_y$ = yield strength of metal (ksi) (12.7.2.3)
$f'_c$ = compressive strength of concrete (ksi) (12.4.2.2) (12.10.4.2.4c)
$f_{cr}$ = critical buckling stress (ksi) (12.7.2.4)
$f_s$ = maximum stress in reinforcing steel at service limit state (ksi) (C12.11.4)
$f_y$ = specified yield point for reinforcing steel (ksi) (12.10.4.2.4a)
$H$ = rise of culvert (ft); height of cover from the box culvert rise to top of pavement (ft); height of cover over crown (ft); height of fill over top of pipe or culvert (ft) (C12.6.2.2.5) (12.9.4.2) (12.9.4.4) (12.9.4.5) (12.10.2.1) (12.12.3.7) (12.15.6.3)
$HAF$ = horizontal arching factor (12.10.2.1)
$H_D$ = vertical distance from mid-depth of corrugation to top grade (12.8.9.4)
$H_{design}$ = design height of cover above top of culvert or above crown of arches or pipes (ft) (C12.6.2.2.5)
$H_L$ = headwall strip reaction (kip) (C12.6.2.2.5)
$H_{min}$ = Minimum allowable cover dimension (C12.6.6.3)
$H_w$ = depth of water table above springline of pipe (ft); height of water over top of pipe (ft) (12.12.3.7) (12.15.6.3)
$H_1$ = depth of crown of culvert below ground surfaces (ft); height of cover above the footing to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
$H_2$ = actual height of cover above top of culvert or above crown of arches or pipes (ft); height of cover from the structure springline to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
$h$ = vertical distance from the top of cover for design height to point of horizontal load application (ft); wall thickness of pipe or box culvert (in.); height of ground surface above top of pipe (ft) (C12.6.2.2.5) (12.10.4.2.4a) (C12.11.4)
$I$ = moment of inertia (in.$^4$/in.) (12.7.2.6) (12.13.3.5)
$ID$ = inside diameter (in.) (12.6.6.3)
$I_p$ = moment of inertia of pipe profile per unit length of pipe (in.$^4$); moment of inertia of the fiber-reinforced pipe wall per unit length (in.$^4$/in.) (12.8.9.6) (12.12.2.2) (12.15.5.2)
$i$ = coefficient for effect of axial force at service limit state, $f_s$ (12.10.4.2.4d) (C12.11.4)
$j$ = coefficient for moment arm at service limit state, $f_s$ (12.10.4.2.4d) (C12.11.4)
$K$ = ratio of the unit lateral effective soil pressure to unit vertical effective soil pressure, i.e., Rankine coefficient of active earth pressure (12.9.4.2)
$K_a$ = factor for uncertainty in level of groundwater table (12.12.3.8)
$K_b$ = bedding coefficient (12.12.2.2)
$K_h$ = lateral earth pressure for culvert under sloping ground (psf/lf) (C12.6.2.2.5)
$K_{h1}$ = lateral earth pressure distribution acting on upslope surface of culvert (psf/lf) (C12.6.2.2.5)
$K_{h2}$ = lateral earth pressure distribution acting on downslope surface of culvert (psf/lf) (C12.6.2.2.5)
$K_t$ = time factor as specified in Table 12.12.3.10.1b-1 (12.12.3.10.1b)
$K_{wa}$ = factor for uncertainty in level of ground water table (C12.12.3.8)
$K_{\gamma E}$ = installation factor (12.12.3.5)
$k$ = soil stiffness factor; edge support coefficient; plate buckling coefficient (12.7.2.4) (C12.13.3.3) (12.12.3.10.1b)

$L$ = distance along length of culvert from expansion joint to the centerline of the headwall (ft); length of stiffening rib on leg (in.) (C12.6.2.2.5) (12.9.4.1)
$LLDF$ = live load distribution factor as specified in Article 3.6.1.2.6 (12.7.2.2)
$L_0$ = length of live load surface contact area parallel to pipe diameter as specified in Article 3.6.1.2.5 (in.) (12.6.1)
$L_w$ = lane width (ft); horizontal live load distribution width in the circumferential direction, at the elevation of the crown (in.) (12.8.4.2) (12.12.3.5)
$\ell_d$ = development length (12.10.4.4.3)
$\ell_{hd}$ = basic development length of welded deformed wire reinforcement (in) (12.10.4.4.4)
$\ell_w$ = live load patch length at depth $H$ as specified in Article 3.6.1.2.6 (12.7.2.2)
$M_{d\ell}$ = dead load moment (kip-ft/ft); sum of the nominal crown and haunch dead load moments (kip-ft/ft) (12.9.4.2)
$M_{d\ell u}$ = factored dead load moment as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
$M_{\ell\ell}$ = live load moment (kip-ft/ft); sum of the nominal crown and haunch live load moments (kip-ft/ft) (12.9.4.2)
$M_{\ell\ell u}$ = factored live load moment as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
$M_n$ = factored moment resistance (12.8.9.5)
$M_{nu}$ = factored moment acting on cross-section width, $b$, as modified for effects of compressive or tensile thrust (kip-in./ft) (12.10.4.2.6)
$M_P$ = plastic moment capacity of deep corrugated structure (k-ft/ft) (12.8.9.4)
$M_p$ = plastic moment capacity of section (12.8.9.5)
$M_{pc}$ = crown plastic moment capacity (kip-ft/ft) (12.9.4.3)
$M_{ph}$ = haunch plastic moment capacity (kip-ft/ft) (12.9.4.3)
$M_s$ = flexural moment at service limit state (kip-in./ft); moment acting on a cross-section of width, $b$, at service limit state taken as an absolute value in design equations (kip-in./ft); secant constrained soil modulus as specified in Table 12.12.3.5-1 or Table 12.12.3.5-3 (ksi) (12.8.9.6) (12.10.4.2.4d) (C12.11.4) (12.12.2.2) (12.12.3.5)
$M_{thick}$ = adjusted moment (12.10.4.2.2)
$M_{thin}$ = moment calculated using thin ring theory (12.10.4.2.2)
$M_u$ = factored applied moment; ultimate moment acting on cross-section width, $b$ (kip-in./ft) (12.8.9.5) (12.10.4.2.4a)
$N_s$ = axial thrust acting on a cross-section width, $b$, at service limit state taken as positive when compressive and negative when tensile (kip/ft) (12.10.4.2.4d) (C12.11.4)
$N_u$ = axial thrust acting on cross-section width, $b$, at strength limit state (kip/ft) (12.10.4.2.4a)
$n$ = number of adjoining traffic lanes (12.8.4.2)
$P_{Brg}$ = allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf) (12.8.5.3)
$P_c$ = proportion of total moment carried by crown of metal box culvert (12.9.4.3)
$P_{FD}$ = factored dead load vertical crown pressure as specified in Article 12.12.3.4 with VAF taken as 1.0 and $D_o$ taken as $S$ (ksf) (12.7.2.2)
$P_{FL}$ = factored live load vertical crown pressure as specified in Article 12.12.3.4 (ksf) (12.7.2.2)
$P_L$ = live load pressure as specified in Article 3.6.1.2.6 (psi) (12.12.2.2) (12.15.5.2)
$P_{sp}$ = soil prism pressure evaluated at pipe springline as specified in Article 12.12.3.7 (psi); soil prism pressure ($EV$), evaluated at the top of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi); soil prism pressure ($EV$), evaluated at the crown of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi) (12.12.2.2) (12.15.5.2) (12.15.6.3)
$P_{st}$ = stub compression capacity from T 341 (lb/in.) (12.12.3.10.1b)
$P_u$ = design factored load (psi) (12.12.3.5)
$P_w$ = hydrostatic water pressure (psi) (12.12.3.8)
$P_1$ = horizontal pressure from the structure at a distance, $d_1$ (ksf) (12.8.5.3)
$p$ = positive projection ratio (12.10.4.3.2a)
$q$ = ratio of the total lateral pressure to the total vertical pressure (12.10.4.3.2a)
$R$ = rise of structure (ft); rise of box culvert or long-span structural plate structures (ft); average radius of the concrete pipe; radius to centroid of pipe wall profile (in.) (12.8.4.1) (12.9.4.1) (12.10.4.2.2) (12.12.2.2) (12.12.3.5)
$R_{AL}$ = axle load correction factor (12.9.4.6)
$R_b$ = nominal axial force in culvert wall to cause general buckling (12.8.9.6)
$R_c$ = corner radius of the structure (ft); concrete strength correction factor (12.8.5.3) (12.9.4.6)
$R_f$ = factor related to required relieving slab thickness, applicable for box structures where the span is less than 26.0 ft (12.9.4.6)
$R_H$ = horizontal footing reaction component (kip/ft) (12.8.4.2) (12.9.4.3)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$R_h$ = haunch moment reduction factor; correction factor for backfill soil geometry (12.8.9.6) (12.9.4.3) (12.12.3.10.1e)
$R_n$ = nominal resistance (klf) (12.5.1)
$R_r$ = factored resistance (klf); factored resistance to thrust (kip/ft) (12.5.1)
$R_T$ = top arc radius of long-span structural plate structures (ft) (12.8.3.2)
$R_t$ = factored thrust resistance (12.8.9.5)
$R_V$ = vertical footing reaction component (kip/ft) (12.8.4.2)
$R_w$ = water buoyancy factor (12.15.6.3)
$R_\phi$ = ($\phi_r/\phi_f$); ratio of resistance factors for radial tension and moment specified in Article 12.5.5 (12.10.4.2.4c)
$r$ = radius of gyration (in.); radius to centerline of concrete pipe wall (in.) (12.7.2.4) (12.10.4.2.5)
$r_c$ = radius of crown (ft) (12.9.4.1)
$r_h$ = radius of haunch (ft) (12.9.4.1)
$r_s$ = radius of the inside reinforcement (in.) (12.10.4.2.4c)
$r_{sd}$ = settlement ratio parameter (12.10.4.3.2a)
$S$ = pipe, tunnel, or box diameter or span (in. or ft as indicated); culvert span (ft); span of structure between springlines of long-span structural plate structures (ft); box culvert span (ft) (12.6.6.3) (C12.6.7) (12.7.2.2) (12.7.2.4) (12.8.4.1) (12.8.4.2) (12.8.9.6) (12.9.4.1) (12.9.4.2) (12.9.4.5) (12.12.3.6)
$S_b$ = long-term ring-bending strain (in./in.) (12.15.3.2)
$S_H$ = hoop stiffness factor (12.12.3.5)
$S_i$ = internal diameter or horizontal span of the pipe (in.) (12.10.4.2.4b)
$S_\ell$ = spacing of circumferential reinforcement (in.) (12.10.4.2.4d)
$S_1$, $S_2$ = shear forces acting along culvert bearing lines (lbs.) (C12.6.2.2.5)
$s_v$ = spacing of stirrups (in.) (12.10.4.2.6)
$T$ = total dead load and live load thrust in the structure (kip/ft) (12.8.5.3)
$T_f$ = factored thrust (12.8.9.5)
$T_L$ = factored thrust per unit length (kip/ft) (12.7.2.2)
$T_s$ = service thrust per unit length (lb/in.) (12.12.3.5)
$T_u$ = factored thrust per unit length (lb/in.) (12.12.3.5)
$t$ = required thickness of cement concrete relieving slab (in.); thickness of element (in.) (12.9.4.6) (12.10.4.2.2) (12.12.3.10.1b)
$t_b$ = basic thickness of cement concrete relieving slab (in.); clear cover over reinforcement (in.) (12.9.4.6) (12.10.4.2.4d)
$V$ = unfactored footing reaction (kip/ft) (12.9.4.5)
$VAF$ = vertical arching factor (12.7.2.2) (12.10.2.1)
$V_c$ = factored shear force acting on cross-section width, $b$, which produces diagonal tension failure without stirrup reinforcement (kip/ft) (12.10.4.2.6)
$V_{DL}$ = $[H_2(S) - A_T]\ \gamma_s/2$ (kip/ft) (12.8.4.2)
$V_L$ = headwall strip reaction (kip) (C12.6.2.2.5)
$V_{LL}$ = $n(A_L)/(8 + 2\ H_1)$ (kip/ft) (12.8.4.2)
$V_n$ = nominal shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft) (12.10.4.2.5)
$V_r$ = factored shear resistance per unit length (kip/ft) (12.10.4.2.5)
$V_u$ = ultimate shear force acting on cross-section width, $b$ (kip/ft) (12.10.4.2.5)
$W_E$ = total unfactored earth load on pipe or liner (kip/ft) (12.10.2.1)
$W_F$ = fluid load in the pipe (kip/ft) (12.10.4.3.1)
$W_L$ = total unfactored live load on unit length pipe specified in Article 12.10.2.3 (kip/ft) (12.10.4.3.1)
$W_T$ = total dead and live load on pipe or liner (kip/ft) (12.10.4.3.1)
$w$ = unit weight of soil (pcf); total clear width of element between supporting elements (in.) (12.10.2.1) (12.12.3.10.1b)
$w_t$ = tire patch width as specified in Article 3.6.1.2.5 (in.) (12.7.2.2)
$x$ = parameter which is a function of the area of the vertical projection of the pipe over which active lateral pressure is effective (12.10.4.3.2a)
$\alpha$ = skew angle between the highway centerline or tangent thereto and the culvert headwall (degrees) (C12.6.2.2.5)
$\beta$ = angle of fill slope measured from horizontal (degrees) (C12.6.2.2.5)
$\gamma_b$ = unit weight of buoyant soil (lb/ft$^3$) (12.12.3.7)
$\gamma_{EV}$ = load factor for vertical pressure from dead load of earth fill; load factor for vertical earth pressure (12.12.3.5) (12.12.3.10.2b) (12.15.6.3)
$\gamma_{LL}$ = load factor for live load (12.12.3.5)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$\gamma_s$ = unit weight of backfill (kcf); soil unit weight (kcf); wet unit weight of soil (lb/ft$^3$) (12.8.4.2) (C12.9.2) (12.9.4.2) (12.9.4.5) (12.11.2.2) (12.12.3.7) (12.13.2.1)
$\gamma_w$ = unit weight of water (lb/ft$^3$) (12.12.3.8) (12.15.6.3)
$\gamma_{WA}$ = load factor for hydrostatic pressure (12.12.3.5)
$\Delta$ = calculated differential settlements across the structure taken from springline-to-springline (12.8.4.1); return angle of the structure (degrees) (12.8.4.2); haunch radius included angle (12.9.4.1)
$\Delta_A$ = total allowable deflection of pipe (in.) (12.12.2.2) (12.15.4)
$\Delta_f$ = deflection of pipe due to flexure (in.) (12.12.3.10.2b)
$\Delta_t$ = total deflection of pipe (in.) (12.12.2.2)
$\varepsilon_{bck}$ = nominal strain capacity for general buckling (in./in.) (12.12.3.10.1e)
$\varepsilon_{fb}$ = factored buckling strain demand (in./in.) (12.15.6.3)
$\varepsilon_f$ = factored strain due to flexure (in./in.) (12.12.3.10.2b)
$\varepsilon_{sc}$ = service compressive strain as specified in Article 12.12.3.10.1c (in./in.) (12.12.2.2)
$\varepsilon_{uc}$ = factored compressive strain due to thrust (12.12.3.10.1c)
$\varepsilon_{yc}$ = factored compressive strain limit as specified in Table 12.12.3.3-1 (12.12.3.10.1b)
$\varepsilon_{yt}$ = service long-term strain limit as specified in Table 12.12.3.3-1 (12.12.3.10.2b)
$\eta_{EV}$ = load modifier, specified in Article 1.3.2, as it applies to vertical earth loads on culverts (12.12.3.5)
$\eta_{LL}$ = load modifier, specified in Article 1.3.2, as it applies to live loads on culverts (12.12.3.5)
$\theta$ = rotation of the structure (C12.8.4.1)
$\lambda$ = slenderness factor (12.12.3.10.1b)
$\nu$ = Poisson's ratio of soil (12.12.3.10.1e)
$\rho$ = effective width factor (12.10.4.2.5) (12.12.3.10.1b)
$\phi$ = resistance factor (12.5.1) (12.5.5) (12.7.2.3)
$\phi_b$ = resistance factor for general buckling (12.5.5) (12.8.9.6)
$\phi_{bck}$ = resistance factor for global buckling (12.5.5) (12.12.3.10.1e)
$\phi_f$ = resistance factor for flexure (12.5.5) (12.10.4.2.4c)
$\phi_h$ = resistance factor for plastic hinge (12.5.5)
$\phi_r$ = resistance factor for radial tension (12.5.5) (12.10.4.2.4c) (12.10.4.2.6)
$\phi_s$ = resistance factor for soil stiffness, $\phi_s = 0.9$; resistance factor for soil pressure (12.5.5) (12.8.9.6) (12.12.3.5) (12.12.3.10.1e)
$\phi_T$ = resistance factor for thrust effects (12.12.3.10.1d)
$\Psi$ = central angle of pipe subtended by assumed distribution of external reactive force (degrees) (12.10.4.2.1)
$\omega$ = spacing of corrugation (in.) (12.12.3.10.1b)

### 12.3.1—Abbreviations

*GC*: clayey gravel
*GM*: silty gravel
*GP*: poorly-graded gravel
*GW*: well-graded gravel
*PE*: polyethylene
*PL*: prism load
*PP:* polypropylene
*PVC*: polyvinyl chloride
*SC*: clayey sand
*SM*: silty sand
*SP*: poorly-graded sand
*SW*: well-graded sand

## 12.4—SOIL AND MATERIAL PROPERTIES

### 12.4.1—Determination of Soil Properties

#### 12.4.1.1—General

Subsurface exploration shall be carried out to determine the presence and influence of geologic and environmental conditions that may affect the performance of buried structures. For buried structures

**C12.4.1.1**

The following information may be useful for design:

- Strength and compressibility of foundation materials;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

supported on footings and for pipe arches and large diameter pipes, a foundation investigation should be conducted to evaluate the capacity of foundation materials to resist the applied loads and to satisfy the movement requirements of the structure.

- Chemical characteristics of soil and surface waters, e.g., pH, resistivity, and chloride content of soil and pH, resistivity, and sulfate content of surface water;
- Stream hydrology, e.g., flow rate and velocity, maximum width, allowable headwater depth, and scour potential; and
- Performance and condition survey of culverts in the vicinity.

**12.4.1.2—Foundation Soils**

The type and anticipated behavior of the foundation soil shall be considered for stability of bedding and settlement under load.

**C12.4.1.2**

Refer to Article 10.4 for general guidance regarding foundation soil properties. The performance of rigid pipes is dependent on foundation and bedding stability.

**12.4.1.3—Envelope Backfill Soils**

The type, compacted density, and strength properties of the soil envelope adjacent to the buried structure shall be established. The backfill soils comprising the soil envelope shall conform to the requirements of AASHTO M 145 as follows:

- For standard flexible pipes and concrete structures: A-1, A-2, or A-3 (GW, GP, SW, SP, GM, SM, SC, GC),
- For metal box culverts and long-span structures with cover less than 12.0 ft: A-1, A-2-4, A-2-5, or A-3 (GW, GP, SW, SP, GM, SM, SC, GC),
- For long-span metal structures with cover not less than 12.0 ft: A-1 or A-3 (GW, GP, SW, SP, GM, SM),
- For structural plate culverts with deep corrugations: A-1, A-2-4, A-2-5, or A-3 (ASTM D2487) (GW, GP, SW, SP, GM, SM, SC, GC) and the culvert manufacturer's requirements, and
- For thermoplastic, fiberglass, and steel-reinforced thermoplastic culverts; bedding; and backfill materials: A-1, A-2-4, A-2-5, or A-3 soils. A maximum of 50 percent of the particle sizes may pass the No. 100 sieve and a maximum of 20 percent may pass the No. 200 sieve.

**C12.4.1.3**

Refer to Sections 26, 27, and 30 of the *AASHTO LRFD Bridge Construction Specifications* for compaction criteria of soil backfill for flexible and rigid culverts.

Refer to ASTM D2487, Standard Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System), for further information on equivalent soil classifications.

Wall stresses in buried structures are sensitive to the relative stiffness of the soil and pipe. Buckling stability of flexible culverts is dependent on soil stiffness.

In the selection of a type of backfill for the envelope, the quality of the material and its suitability for achieving the requirements of the design should be considered. The order of preference for selecting envelope backfill based on quality may be taken as follows:

- Angular, well-graded sand and gravel;
- Nonangular, well-graded sand and gravel;
- Flowable materials, e.g., cement–soil–fly ash mixtures, which result in low density/low strength backfill, for trench applications only;
- Uniform sand or gravel, provided that placement is confirmed to be dense and stable, but which may require a soil or geofabric filter to prevent the migration of fines;
- Clayey sand or gravel of low plasticity; and
- Stabilized soil, which should be used only under the supervision of an Engineer familiar with the behavior of the material.

The restriction on materials passing the No. 100 sieve and No. 200 sieve for thermoplastic, fiberglass, and steel-reinforced thermoplastic culverts is intended to eliminate uniform fine sands for use as pipe embedment. Such materials are difficult to work with, are sensitive to moisture content, and do not provide support comparable to coarser or more broadly graded materials at the same percentage of maximum density. The Engineer may permit exceptions to these restrictions in special cases. If so, a suitable plan should be submitted for control of moisture content and compaction procedures. These silty

All rights reserved. Duplication is a violation of applicable law.

and clayey materials should never be used in a wet site. Increased inspection levels should be considered if such a plan is approved.

### 12.4.2—Materials

#### 12.4.2.1—Aluminum Pipe and Structural Plate Structures

Aluminum for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 196 (ASTM B745). Aluminum for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 219 (ASTM B746).

#### 12.4.2.2—Concrete

Concrete shall conform to Article 5.4, except that $f'_c$ may be based on cores.

#### 12.4.2.3—Precast Concrete Pipe

Precast concrete pipe shall comply with the requirements of AASHTO M 170M and M 170 (ASTM C76M and C76), M 242M/M 242 (ASTM C655M and C655), or ASTM C1765. Design wall thickness other than the standard wall dimensions may be used, provided that the design complies with all applicable requirements of this Section.

#### 12.4.2.4—Precast Concrete Structures

Precast concrete arch, elliptical, and box structures shall comply with the requirements of AASHTO M 206M/M 206 (ASTM C506M and C506), M 207M/M 207 (ASTM C507M and C507), M 259 (ASTM C789), and M 273 (ASTM C850).

#### 12.4.2.5—Steel Pipe and Structural Plate Structures

Steel for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 36 (ASTM A760/A760M). Steel for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 167M/M 167 (ASTM A761/A761M).

#### 12.4.2.6—Deep Corrugated Structures

Steel for deep corrugated structural plate shall comply with the requirements of AASHTO M 167M/M 167. Deep corrugated structural plate may be reinforced.

**C12.4.2.6**

Reinforcement for deep corrugated structures may consist of structural shapes, or deep corrugated structural plate meeting the requirements of AASHTO M 167M/M 167, with or without nonshrink grout, complete with shear studs.

#### 12.4.2.7—Steel Reinforcement

Reinforcement shall comply with the requirements of Article 5.4.3, and shall conform to one of the following: AASHTO M 31M/M 31 (ASTM A615/A615M),

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

M 32M/M 32, M 55M/M 55, M 221M/M 221, M 336M/M 336, ASTM A1064/A1064M, or ASTM A706/A706M.

The nominal yield strength shall be the minimum as specified for the grade of steel selected, but shall not exceed 80 ksi.

#### 12.4.2.8—Thermoplastic Pipe

Plastic pipe may be solid wall, corrugated, or profile wall and may be manufactured of polyethylene (PE) or polyvinyl chloride (PVC).

PE pipe shall comply with the requirements of ASTM F714 for solid wall pipe, AASHTO M 294 for corrugated pipe, and ASTM F894 for profile wall pipe.

PVC pipe shall comply with the requirements of AASHTO M 278 for solid wall pipe, ASTM F679 for solid wall pipe, and AASHTO M 304 for profile wall pipe.

#### 12.4.2.9—Fiberglass Pipe

Glass-fiber-reinforced (fiberglass) pipe shall be solid wall and manufactured from glass-fiber-reinforced thermosetting resins, with or without aggregates or liners, and shall comply with the requirements of ASTM D3262. For pipe exposed to sunlight after installation, in addition to the requirements of ASTM D3262, the liner and surface layers shall provide protection from ultraviolet exposure for the design life of the product.

#### C12.4.2.9

ASTM D3262 specifies pipe for use in conveyance of sanitary sewer, storm water, and some industrial waste, primarily in buried applications. The standard includes pipes with stiffness from 9 to 72 psi. The lowest pipe stiffness allowed, 9 psi, should only be used for specific applications (e.g., concrete encasement), where the pipe is not subjected to typical installation forces such as backfill compaction.

#### 12.4.2.10—Steel-Reinforced Thermoplastic Culverts

Steel-reinforced thermoplastic (SRPE) culverts have a profile wall which may be ribbed or corrugated. Ribbed profile wall steel-reinforced thermoplastic culverts shall meet the requirements of AASHTO M 335 and MP 42 for larger diameters (66.0 to 120 in.). Corrugated profile wall steel-reinforced thermoplastic culverts shall meet requirements of AASHTO MP 42.

## 12.5—LIMIT STATES AND RESISTANCE FACTORS

### 12.5.1—General

Buried structures and their foundations shall be designed by the appropriate methods specified in Articles 12.7 through 12.15 to resist the load combinations specified in Articles 12.5.2 and 12.5.3.

The factored resistance, $R_r$, shall be calculated for each applicable limit state as:

$$R_r = \phi R_n \qquad (12.5.1\text{-}1)$$

where:

$R_n$ = the nominal resistance
$\phi$ = the resistance factor specified in Table 12.5.5-1

### C12.5.1

Procedures for determining nominal resistance are provided in Articles 12.7 through 12.15 for:

- Metal pipe, pipe arches, and arch structures;
- Long-span and deep corrugated structural plate structures;
- Structural plate box structures;
- Reinforced precast concrete pipe;
- Reinforced concrete cast-in-place and precast box structures and reinforced cast-in-place arches;
- Thermoplastic pipe;
- Steel tunnel liner plate;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Precast reinforced concrete three-sided structures;
- Fiberglass pipe; and
- Steel-reinforced thermoplastic culverts.

### 12.5.2—Service Limit State

Buried structures shall be investigated at Service Load Combination I, as specified in Table 3.4.1-1.

- Deflection of metal structures, tunnel liner plate, thermoplastic pipe, and fiberglass pipe, and
- Crack width in reinforced concrete structures.

### C12.5.2

Deflection of a tunnel liner depends significantly on the amount of overexcavation of the bore and is affected by delay in backpacking or inadequate backpacking. The magnitude of deflection is not primarily a function of soil modulus or the liner plate properties, so it cannot be computed with usual deflection formulae.

Where the tunnel clearances are important, the designer should oversize the structure to allow for deflection.

### 12.5.3—Strength Limit State

Buried structures and tunnel liners shall be investigated for construction loads and at Strength Load Combinations I and II, as specified in Table 3.4.1-1, as follows:

- For metal structures:
  - Wall area
  - Buckling
  - Seam failure
  - Flexibility limit for construction
  - Flexure of box and deep corrugated structures only
- For concrete structures:
  - Flexure
  - Shear
  - Thrust
  - Radial tension
- For thermoplastic pipe:
  - Wall area
  - Buckling
  - Flexibility limit
- For tunnel liner plate:
  - Wall area
  - Buckling
  - Seam strength
  - Construction stiffness
- For fiberglass pipe:
  - Flexure
  - Buckling
  - Flexibility limit

### C12.5.3

Strength Load Combinations III and IV and the extreme event limit state do not control due to the relative magnitude of loads applicable to buried structures as indicated in Article 12.6.1. Buried structures have been shown not to be controlled by fatigue.

Flexibility limit requirement is waived for some metal structures. See design provisions in Article 12.8.

Thermoplastic pipe has many profile wall geometries and some of these are made up of thin sections that may be limited based on local buckling. The strength limit state for wall area includes evaluating the section capacity for local buckling.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- For steel-reinforced thermoplastic culverts:
  - Wall area
  - Buckling
  - Flexibility limit for construction

Steel-reinforced thermoplastic culverts are comprised of thin sections that may be limited due to local buckling. The strength limit state for wall area includes evaluating the section capacity for local buckling.

### 12.5.4—Load Modifiers and Load Factors

Load modifiers shall be applied to buried structures and tunnel liners as specified in Article 1.3, except that the load modifiers for construction loads shall be taken as 1.0. For strength limit states, buried structures shall be considered redundant. Operational classification shall be determined on the basis of continued function and/or safety of the roadway.

### 12.5.5—Resistance Factors

Resistance factors for buried structures shall be taken as specified in Table 12.5.5-1. Values of resistance factors for the geotechnical design of foundations for buried structures shall be taken as specified in Section 10.

**C12.5.5**

The standard installations for direct design of concrete pipe were developed based on extensive parameter studies using the soil–structure interaction program, SPIDA. Although past research validates that SPIDA soil–structure models correlate well with field measurements, variability in culvert installation methods and materials suggests that the design for Type I installations be modified. This revision reduces soil–structure interaction for Type I installations by ten percent until additional performance documentation on installation in the field is obtained.

The new thermoplastic design method evaluates more load conditions than prior specifications. Separate resistance factors are provided for each mode of behavior. The resistance factor for buckling is set at 0.7 and preserves the same level of safety as prior editions of these Specifications with the inclusion of the installation factor of Article 12.12.3.5. Buckling is an undesirable failure mode for culverts. Buckling can result in near total collapse of the culvert and blockage of the waterway.

## 12.5.6—Flexibility Limits and Construction Stiffness

### 12.5.6.1—Corrugated Metal Pipe and Structural Plate Structures

Flexibility factors for corrugated metal pipe, structural plate structures, and steel-reinforced thermoplastic culverts shall not exceed the values specified in Table 12.5.6.1-1.

**C12.5.6.1**

Limits on construction stiffness and plate flexibility are construction requirements that do not represent any limit state in service.

**Table 12.5.6.1-1—Flexibility Factor Limit**

| Type of Construction Material | Corrugation Size (in.) | Flexibility Factor (in./kip) |
|---|---|---|
| Steel Pipe | 0.25 | 43 |
| | 0.5 | 43 |
| | 1.0 | 33 |
| Aluminum Pipe | 0.25 and 0.50 | |
| | 0.060 Material Thk. | 31 |
| | 0.075 Material Thk. | 61 |
| | All Others | 92 |
| | 1.0 | 60 |
| Steel Plate | 6.0 × 2.0 | |
| | Pipe | 20 |
| | Pipe-Arch | 30 |
| | Arch | 30 |
| Aluminum Plate | 9.0 × 2.5 | |
| | Pipe | 25 |
| | Pipe-Arch | 36 |
| | Arch | 36 |
| Steel-Reinforced Thermoplastic Pipe | | 68 |

### 12.5.6.2—Spiral Rib Metal Pipe and Pipe Arches

Flexibility factors for spiral rib metal pipe and pipe arches shall not exceed the values, specified in Table 12.5.6.2-1, for embankment installations conforming to the provisions of Articles 12.6.6.2 and 12.6.6.3 and for trench installations conforming to the provisions of Articles 12.6.6.1 and 12.6.6.3.

**Table 12.5.6.2-1—Flexibility Factor Limits**

| Material | Condition | Corrugation Size (in.) | Flexibility Factor (in./kip) |
|---|---|---|---|
| Steel | Embankment | 0.75 × 0.75 × 7.5 | $217I^{1/3}$ |
| | | 0.75 × 1.0 × 11.5 | $140I^{1/3}$ |
| | Trench | 0.75 × 0.75 × 7.5 | $263I^{1/3}$ |
| | | 0.75 × 1.0 × 11.5 | $163I^{1/3}$ |
| Aluminum | Embankment | 0.75 × 0.75 × 7.5 | $340I^{1/3}$ |
| | | 0.75 × 1.0 × 11.5 | $175I^{1/3}$ |
| | Trench | 0.75 × 0.75 × 7.5 | $420I^{1/3}$ |
| | | 0.75 × 1.0 × 11.5 | $215I^{1/3}$ |

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Values of inertia, $I$, for steel and aluminum pipes and pipe arches shall be taken as tabulated in Tables A12-2 and A12-5.

**12.5.6.3—Thermoplastic and Fiberglass Pipe**

Flexibility factor, $FF$, of thermoplastic and fiberglass pipe shall not exceed 95.0 in./kip.

**C12.5.6.3**

PE and PVC are thermoplastic materials that exhibit higher flexibility factors at high temperatures and lower flexibility factors at low temperatures. The specified flexibility factor limits are defined in relation to pipe stiffness values in accordance with ASTM D2412 at 73.4 degrees F.

**12.5.6.4—Steel Tunnel Liner Plate**

Construction stiffness, $C_s$, in kip/in., shall not be less than the following:

- Two-flange liner plate

  $C_s \geq 0.050$ (kip/in.)

- Four-flange liner plate

  $C_s \geq 0.111$ (kip/in.)

**C12.5.6.4**

Assembled liner using two- and four-flange liner plates does not provide the same construction stiffness as a full steel ring with equal stiffness.

## 12.6—GENERAL DESIGN FEATURES

### 12.6.1—Loading

Buried structures shall be designed for force effects resulting from horizontal and vertical earth pressure, pavement load, live load, and vehicular dynamic load allowance. Earth surcharge, live load surcharge, downdrag loads, and external hydrostatic pressure shall be evaluated where construction or site conditions warrant. Water buoyancy loads shall be evaluated for buried structures with inverts below the water table to control flotation, as indicated in Article 3.7.2. Earthquake loads should be considered only where buried structures cross active faults.

For vertical earth pressure, the maximum load factor from Table 3.4.1-2 shall apply.

Wheel loads shall be distributed through earth fills according to the provisions of Article 3.6.1.2.6.

**C12.6.1**

Buried structures benefit from both earth shelter and support that reduce or eliminate from concern many of the loads and load combinations of Article 3.4. Wind, temperature, vehicle braking, and centrifugal forces typically have little effect due to earth protection. Structure dead load, pedestrian live load, and ice loads are insignificant in comparison with force effects due to earth fill loading. External hydrostatic pressure, if present, can add significantly to the total thrust in a buried pipe.

Vehicular collision forces are applicable to appurtenances such as headwalls and railings only. Water, other than buoyancy and vessel collision loads, can act only in the noncritical longitudinal direction of the culvert.

Due to the absence or low magnitude of these loadings, Service Load Combination I, Strength Load Combinations I and II, or construction loads control the design.

The finite element analyses used in the preparation of these metal box structure provisions are based on conservative soil properties of low plasticity clay (*CL*) compacted to 90 percent density as specified in AASHTO T 99. Although low plasticity clay is not considered an acceptable backfill material, as indicated in Article 12.4.1.3, the FEM results have been shown to yield conservative, upperbound moments.

The loading conditions that cause the maximum flexural moment and thrust are not necessarily the same, nor are they necessarily the conditions that will exist at the final configuration.

All rights reserved. Duplication is a violation of applicable law.

### 12.6.2—Service Limit State

#### 12.6.2.1—Tolerable Movement

Tolerable movement criteria for buried structures shall be developed based on the function and type of structure, anticipated service life, and consequences of unacceptable movements.

#### 12.6.2.2—Settlement

*12.6.2.2.1—General*

Settlement shall be determined as specified in Article 10.6.2. Consideration shall be given to potential movements resulting from:

- Longitudinal differential settlement along the length of the pipe,
- Differential settlement between the pipe and backfill, and
- Settlement of footings and unbalanced loading of skewed structures extending through embankment slopes.

*12.6.2.2.2—Longitudinal Differential Settlement*

Differential settlement along the length of buried structures shall be determined in accordance with Article 10.6.2.4. Pipes and culverts subjected to longitudinal differential settlements shall be fitted with positive joints to resist disjointing forces meeting the requirements of Sections 26, "Metal Culverts," and 27, "Concrete Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

Camber may be specified for an installation to ensure hydraulic flow during the service life of the structure.

*12.6.2.2.3—Differential Settlement between Structure and Backfill*

*C12.6.2.2.3*

Where differential settlement of arch structures is expected between the structure and the side fill, the foundation should be designed to settle with respect to the backfill.

Pipes with inverts shall not be placed on foundations that will settle much less than the adjacent side fill, and a uniform bedding of loosely compacted granular material should be provided.

The purpose of this provision is to minimize downdrag loads.

*12.6.2.2.4—Footing Settlement*

*C12.6.2.2.4*

Footings shall be designed to provide uniform longitudinal and transverse settlement. The settlement of footings shall be large enough to provide protection against possible downdrag forces caused by settlement of adjacent fill. If poor foundation materials are encountered, consideration shall be given to excavation

Metal pipe arch structures, long-span arch structures, and box culvert structures should not be supported on foundation materials that are relatively unyielding compared with the adjacent sidefill. The use of massive footings or piles to prevent settlement of such structures is not recommended.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

of all or some of the unacceptable material and its replacement with compacted acceptable material.

Footing design shall comply with the provisions of Article 10.6.

Footing reactions for metal box culvert structures shall be determined as specified in Article 12.9.4.5.

The effects of footing depth shall be considered in the design of arch footings. Footing reactions shall be taken as acting tangential to the arch at the point of connection to the footing and to be equal to the thrust in the arch at the footing.

In general, provisions to accommodate uniform settlement between the footings are desirable, provided that the resulting total settlement is not detrimental to the function of the structure.

*12.6.2.2.5—Unbalanced Loading*

Buried structures skewed to the roadway alignment and extending through an embankment fill shall be designed in consideration of the influence of unsymmetrical loading on the structure section.

*C12.6.2.2.5*

Disregard of the effect of lateral unbalanced forces in the headwall design can result in failure of the headwall and adjacent culvert sections.

Due to the complexity of determining the actual load distribution on a structure subjected to unbalanced loading, the problem can be modeled using numerical methods or the following approximate method. The approximate method consists of analyzing 1.0-ft wide culvert strips for the unbalanced soil pressures wherein the strips are limited by planes perpendicular to the culvert centerline. Refer to Figure C12.6.2.2.5-1 for this method of analysis for derivation of force $F$. For semicomplete culvert strips, the strips may be assumed to be supported as shown in the lower part of the plan. The headwall shall be designed as a frame carrying the strip reactions, $V_L$ and $H_L\cos\alpha$, in addition to the concentrated force, $F$, assumed to be acting on the crown. Force $F$ is determined using the equations given herein.

All rights reserved. Duplication is a violation of applicable law.

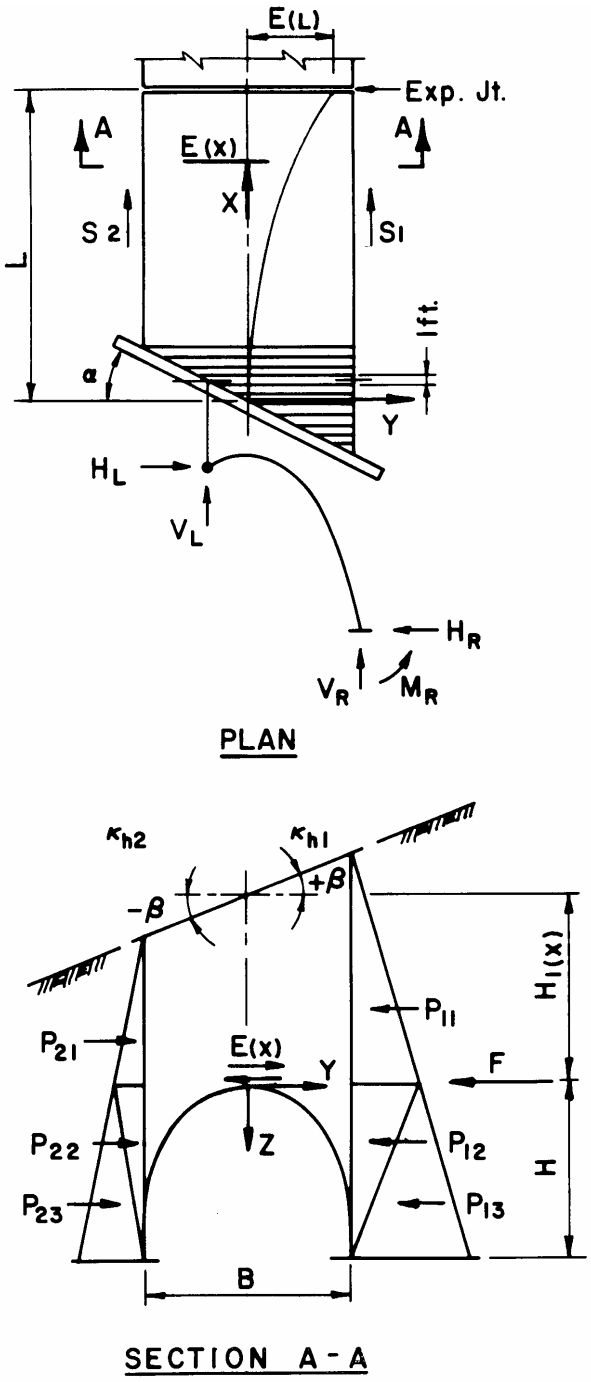

**Figure C12.6.2.2.5-1—Forces on Culvert—Approximate Analysis**

The unbalanced distributed load may be estimated by the following relationships:

$$E(x) = (P_{11} - P_{21}) + \frac{2}{3}(P_{12} - P_{22}) + \frac{1}{3}(P_{13} - P_{23}) \quad \text{(C12.6.2.2.5-1)}$$

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

in which:

$$
\begin{aligned}
P_{11} &= \frac{1}{2}K_{h1}\left(H_{1(x)} + \frac{B}{2}\tan\beta\right)^2 \\
P_{21} &= \frac{1}{2}K_{h2}\left(H_{1(x)} - \frac{B}{2}\tan\beta\right)^2 \\
P_{12} &= \frac{1}{2}K_{h1}H\left(H_{1(x)} + \frac{B}{2}\tan\beta\right) \\
P_{22} &= \frac{1}{2}K_{h2}H\left(H_{1(x)} - \frac{B}{2}\tan\beta\right) \\
P_{13} &= \frac{1}{2}K_{h1}H\left(H + H_{1(x)} + \frac{B}{2}\tan\beta\right) \\
P_{23} &= \frac{1}{2}K_{h2}H\left(H + H_{1(x)} - \frac{B}{2}\tan\beta\right)
\end{aligned}
\qquad \text{(C12.6.2.2.5-2)}
$$

When the pressures are substituted into Eq. C12.6.2.2.5-1, the following results:

$$E(x) = A_2 x^2 + A_1 x + A_0 \qquad \text{(C12.6.2.2.5-3)}$$

in which:

$$
\begin{aligned}
A_2 &= \frac{1}{2}\left(\frac{H_{1(L)}}{L}\right)^2 (K_{h1} - K_{h2}) \\
A_1 &= \frac{1}{2}\left(\frac{H_{1(L)}}{L}\right)[B(K_{h1} + K_{h2})\tan\beta + H(K_{h1} - K_{h2})] \\
A_0 &= \frac{1}{24}[(3B^2\tan^2\beta + 4H^2)(K_{h1} - K_{h2}) \\
&\quad + 6HB(K_{h1} + K_{h2})\tan\beta]
\end{aligned}
\qquad \text{(C12.6.2.2.5-4)}
$$

The support forces for the unbalanced distribution load, $E(x)$, are:

$$
\begin{aligned}
F &= \frac{1}{6}L\sec\alpha(2A_2L^2 + 3A_1L + 6A_0) \\
S_1 &= -\frac{1}{12}\frac{L}{B}[A_2L^2(3L - 2B\tan\alpha) + A_1L(4L \\
&\quad - 3B\tan\alpha) + 6A_0(L - B\tan\alpha)] \\
S_2 &= \frac{1}{12}\frac{L}{B}[A_2L^2(3L + 2B\tan\alpha) + A_1L(4L \\
&\quad + 3B\tan\alpha) + 6A_0(L + B\tan\alpha)]
\end{aligned}
\qquad \text{(C12.6.2.2.5-5)}
$$

For values of $K_h$, see Figure C12.6.2.2.5-2.

All rights reserved. Duplication is a violation of applicable law.

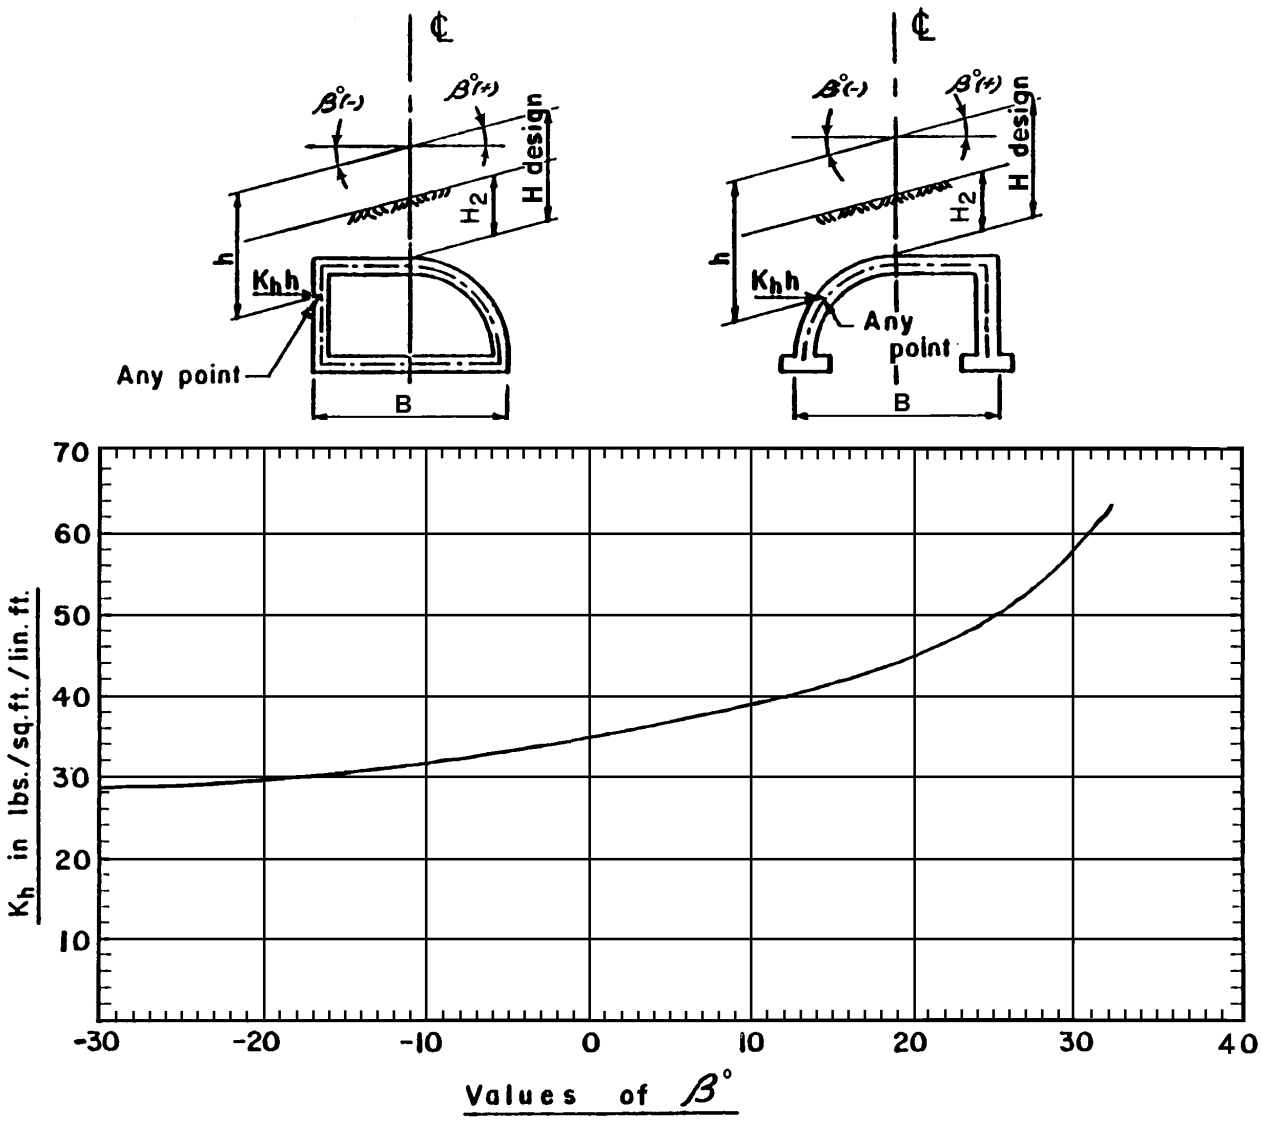

**Figure C12.6.2.2.5-2—Lateral Earth Pressure as a Function of Ground Slope**

#### 12.6.2.3—Uplift

Uplift shall be considered where structures are installed below the highest anticipated groundwater level.

#### C12.6.2.3

To satisfy this provision, the dead load on the crown of the structure should exceed the buoyancy of the culvert, using load factors as appropriate.

### 12.6.3—Safety Against Soil Failure

#### 12.6.3.1—Bearing Resistance and Stability

Pipe structures and footings for buried structures shall be investigated for bearing capacity failure and erosion of soil backfill by hydraulic gradients.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 12.6.3.2—Corner Backfill for Metal Pipe Arches

The corner backfill for metal pipe arches shall be designed to account for corner pressure taken as the arch thrust divided by the radius of the pipe-arch corner. The soil envelope around the corners of pipe arches shall resist this pressure. Placement of select structural backfill compacted to unit weights higher than normal may be specified.

### 12.6.4—Hydraulic Design

Design criteria as specified in Article 2.6 and in the *AASHTO Drainage Manual* (2014) shall apply.

### 12.6.5—Scour

Buried structures shall be designed so that no movement of any part of the structure will occur as a result of scour.

In areas where scour is a concern, the wingwalls shall be extended far enough from the structure to protect the structural portion of the soil envelope surrounding the structure. For structures placed over erodible deposits, a cut-off wall or scour curtain, extending below the maximum anticipated depth of scour or a paved invert, shall be used. The footings of structures shall be placed not less than 2.0 ft below the maximum anticipated depth of scour.

### 12.6.6—Soil Envelope

#### 12.6.6.1—Trench Installations

The minimum trench width shall provide sufficient space between the pipe and the trench wall to ensure sufficient working room to properly and safely place and compact backfill material.

The contract documents shall require that stability of the trench be ensured by either sloping the trench walls or providing support of steeper trench walls in conformance with OSHA or other regulatory requirements.

#### C12.6.6.1

As a guide, the minimum trench width should not be less than the greater of the pipe diameter plus 16.0 in. or the pipe diameter times 1.5 plus 12.0 in. The use of specially designed equipment may enable satisfactory installation and embedment even in narrower trenches. If the use of such equipment provides an installation meeting the requirements of this Article, narrower trench widths may be used as approved by the Engineer.

For trenches excavated in rock or high-bearing soils, decreased trench widths may be used up to the limits required for compaction. For these conditions, the use of a flowable backfill material, as specified in Article 12.4.1.3, allows the envelope to be decreased to within 6.0 in. along each side of the pipe.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.6.6.2—Embankment Installations

The minimum width of the soil envelope shall be sufficient to ensure lateral restraint for the buried structure. The combined width of the soil envelope and embankment beyond shall be adequate to support all the loads on the culvert and to comply with the movement requirements specified in Article 12.6.2.

### C12.6.6.2

As a guide, the minimum width of the soil envelope on each side of the buried structure should not be less than the widths specified in Table C12.6.6.2-1:

**Table C12.6.6.2-1—Minimum Width of Soil Envelope**

| Diameter, $S$ (in.) | Minimum Envelope Width (ft) |
|---|---|
| <24 | $S$/12 |
| 24–144 | 2.0 |
| >144 | 5.0 |

### 12.6.6.3—Minimum Cover

The minimum cover, including a well-compacted granular subbase and base course, shall not be less than that specified in Table 12.6.6.3-1, where:

$S$ = diameter of pipe (in.)
$B_c$ = outside diameter or width of the structure (ft)
$B'_c$ = out-to-out vertical rise of pipe (ft)
$ID$ = inside diameter (in.)

### C12.6.6.3

McGrath et al. (2005) has shown that the significant thermal expansion in thermoplastic pipe can affect pavement performance under shallow fills. Depending on the pipe material and the pavement type above it, the minimum cover may include the pavement thickness and base course, along with the sub-base.

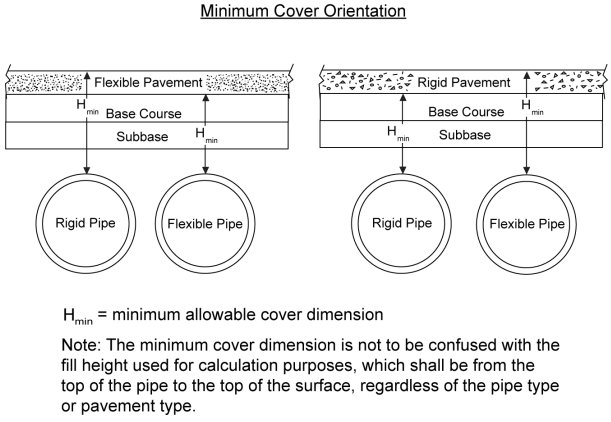

**Figure 12.6.6.3-1—Minimum Cover Orientation**

If the minimum cover provided in Table 12.6.6.3-1 is not sufficient to avoid placement of the pipe within the pavement layer, then the minimum cover should be increased to a minimum of the pavement thickness, unless an analysis is performed to determine the effect on both the pipe and the pavement.

All rights reserved. Duplication is a violation of applicable law.

**Table 12.6.6.3-1—Minimum Cover**

| Type | Condition | Minimum Cover* |
|---|---|---|
| Corrugated Metal Pipe | — | $S/8 \geq 12.0$ in. |
| Spiral Rib Metal Pipe | Steel Conduit | $S/4 \geq 12.0$ in. |
| | Aluminum Conduit where $S \leq 48.0$ in. | $S/2 \geq 12.0$ in. |
| | Aluminum Conduit where $S > 48.0$ in. | $S/2.75 \geq 24.0$ in. |
| Structural Plate Pipe Structures | — | $S/8 \geq 12.0$ in. |
| Long-Span Structural Plate Pipe Structures | — | Refer to Table 12.8.3.1.1-1 |
| Structural Plate Box Structures | — | 1.4 ft. as specified in Article 12.9.1 |
| Deep Corrugated Structural Plate Structures | — | See Article 12.8.9.4 |
| Fiberglass Pipe | — | 12.0 in. |
| Thermoplastic Pipe | Under unpaved areas | $ID/8 \geq 12.0$ in. |
| | Under paved roads | $ID/2 \geq 24.0$ in. |
| Steel-Reinforced Thermoplastic Culverts | — | $S/5 \geq 12.0$ in. |
| Reinforced Concrete Pipe | Under unpaved areas or top of flexible pavement | $B_c/8$ or $B'_c/8$, whichever is greater, $\geq$ 12.0 in. |
| Reinforced Concrete Pipe | Under bottom of rigid pavement | 9.0 in. |
| * Minimum cover taken from top of rigid pavement or bottom of flexible pavement | | |

If soil cover is not provided, the top of precast or cast-in-place reinforced concrete box structures shall be designed for direct application of vehicular loads.

Additional cover requirements during construction shall be taken as specified in Article 30.5.5 of the *AASHTO LRFD Bridge Construction Specifications.*

## 12.6.7—Minimum Spacing between Multiple Lines of Pipe

The spacing between multiple lines of pipe shall be sufficient to permit the proper placement and compaction of backfill below the haunch and between the structures.

Contract documents should require that backfilling be coordinated to minimize unbalanced loading between multiple, closely spaced structures. Backfill should be kept level over the series of structures when possible. The effects of significant roadway grades across a series of structures shall be investigated for the stability of flexible structures subjected to unbalanced loading.

## C12.6.7

As a guide, the minimum spacing between pipes should not be less than that shown in Table C12.6.7-1.

**Table C12.6.7-1—Minimum Pipe Spacing**

| Type of Structure | Minimum Distance Between Pipes (ft) |
|---|---|
| Round Pipes Diameter, $D$ (ft) | |
| <2.0 | 1.0 |
| 2.0–6.0 | $D/2$ |
| >6.0 | 3.0 |
| Pipe Arches Span, $S$ (ft) | |
| <3.0 | 1.0 |
| 3.0–9.0 | $S/3$ |
| 9.0–16.0 | 3.0 |
| Arches Span, $S$ (ft) | |
| All Spans | 2.0 |

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The minimum spacing can be reduced if a flowable backfill material, as specified in Article 12.4.1.3, is placed between the structures.

## 12.6.8—End Treatment

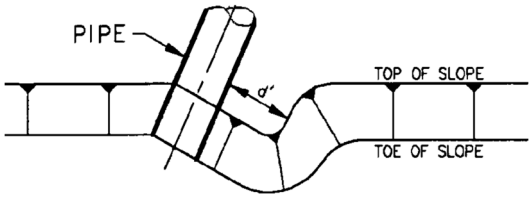
### 12.6.8.1—General

Protection of end slopes shall be given special consideration where backwater conditions occur or where erosion or uplift could be expected. Traffic safety treatments, such as a structurally adequate grating that conforms to the embankment slope, extension of the culvert length beyond the point of hazard, or provision of guide rail, should be considered.

### C12.6.8.1

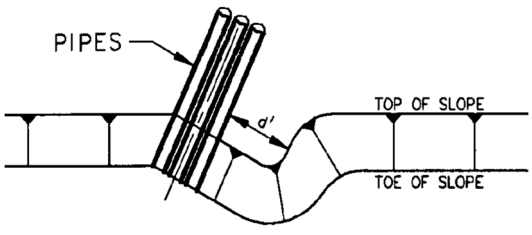
Culvert ends may represent a major traffic hazard.

When backwater conditions occur, pressure flow at the outlet end of culverts can result in uplift of pipe sections having inadequate cover and scour of erosive soils due to high velocities of water flow. Measures to control these problems include anchoring the pipe end in a concrete headwall or burying it in riprap having sufficient mass to resist uplift forces as well as lining outlet areas with riprap or concrete to prevent scour.



### 12.6.8.2—Flexible Culverts Constructed on Skew

The end treatment of flexible culverts skewed to the roadway alignment and extending through embankment fill shall be warped to ensure symmetrical loading along either side of the pipe or the headwall shall be designed to support the full thrust force of the cut end.



### C12.6.8.2

For flexible structures, additional reinforcement of the end is recommended to secure the metal edges at inlet and outlet against hydraulic forces. Reinforcement methods include reinforced concrete or structural steel collars, tension tiebacks or anchors in soil, partial headwalls, and cut-off walls below invert elevation.

As a guide in Figure C12.6.8.2-1, limits are suggested for skews to embankments unless the embankment is warped. It also shows examples of warping an embankment cross-section to achieve a square-ended pipe for single and multiple flexible pipe installations where the minimum width of the warped embankment, $d'$, is taken as 1.50 times the sum of the rise of the culvert and the cover or three times the span of the culvert, whichever is less.

PROPER BALANCE FOR
SINGLE STRUCTURE

PROPER BALANCE FOR
MULTIPLE STRUCTURE

**Figure C12.6.8.2-1—End Treatment of Skewed Flexible Culvert**

All rights reserved. Duplication is a violation of applicable law.

### 12.6.9—Corrosive and Abrasive Conditions

The degradation of culvert material due to corrosion and abrasion is a consideration when selecting material types. The invert of culverts receives the largest impact due to corrosion and abrasion; however, the surrounding soil properties and groundwater may impact other portions of the culvert barrel.

Culvert service life is determined by the owner and is established based on the importance of the culvert. Considerations are given to the roadway classification, average daily traffic, risk of premature failure, and costs to replace.

Ensure the culvert material service life meets or exceeds the culvert service life. Use of different metals, protective linings, increased gauge thickness, or a combination of these methods are commonly used for metal culverts. Additional concrete cover over reinforcing steel or protective coatings are common approaches used in concrete culverts.

**C12.6.9**

Several long-term tests of the field performance of buried structures have resulted in development of empirical guidelines for estimating culvert material service life due to the effects of corrosion and abrasion. A representative listing includes Bellair and Ewing (1984), Koepf and Ryan (1986), Hurd (1984), Meacham et al. (1982), Potter (1988), Funahashi and Bushman (1991), Sagues (2001), NCHRP Synthesis No. 474 (2015), and Sargand (2016).

Commonly-used culvert service life requirements range from 25 to 75 years of service.

The National Corrugated Steel Pipe Association offers an online Service Life Calculator for corrugated steel pipe that requires input of soil resistivity, water pH, FHWA abrasion level (1–4), and a determination if the water contains soft water with $CaCO_3$. FHWA abrasion levels are as follows:

- Level 1—Nonabrasive conditions exist in areas of no bed load and very low velocities. This is the condition assumed for the soil side of drainage pipes.
- Level 2—Low abrasive conditions exist in areas of minor bed loads of sand and velocities of 5.0 ft/s or less.
- Level 3—Moderate abrasive conditions exist in areas of moderate bed loads of sand and gravel and velocities between 5.0 ft/s and 15.0 ft/s.
- Level 4—Severe abrasive conditions exist in areas of heavy bed loads of sand, gravel, and rock and velocities exceeding 15.0 ft/s.

## 12.7—METAL PIPE, PIPE ARCH, ARCH STRUCTURES, AND STEEL-REINFORCED THERMOPLASTIC CULVERTS

### 12.7.1—General

The provisions herein shall apply to the design of buried corrugated and spiral rib metal pipe and structural plate pipe structures.

Corrugated metal pipe and pipe-arches may be of riveted, welded, or lockseam fabrication with annular or helical corrugations. Structural plate pipe, pipe-arches, and arches shall be bolted with annular corrugations only.

The rise-to-span ratio of structural plate arches shall not be less than 0.3.

The provisions of Article 12.8 shall apply to structures with a radius exceeding 13.0 ft.

**C12.7.1**

These structures become part of a composite system comprised of the metal pipe section and the soil envelope, both of which contribute to the structural behavior of the system.

For information regarding the manufacture of structures and structural components referred to herein, AASHTO M 196 (ASTM B745) for aluminum, M 36 (ASTM A760/A760M) for steel corrugated metal pipe and pipe-arches, and M 167M/M 167 (ASTM A761/A761M) for steel and M 219 (ASTM B746) for aluminum structural plate pipe may be consulted.

### 12.7.2—Safety Against Structural Failure

Corrugated and spiral rib metal pipe and pipe arches and structural plate pipe shall be investigated at the strength limit state for:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- wall area of pipe,
- buckling strength, and
- seam resistance for structures with longitudinal seams.

**12.7.2.1—Section Properties**

Dimensions and properties of pipe cross-sections; minimum seam strength; mechanical and chemical requirements for aluminum corrugated and steel corrugated pipe and pipe-arch sections; and aluminum and steel corrugated structural plate pipe, pipe-arch, and arch sections, may be taken as given in Appendix A12.

Dimensions, properties of pipe cross-sections, and material properties for steel-reinforced thermoplastic culverts shall be provided by the pipe manufacturer.

**C12.7.2.1**

Steel-reinforced thermoplastic culverts are pipe sections in which the main load-carrying members are steel ribs or corrugations encapsulated by thermoplastic material that may brace the ribs or corrugations from distortion and buckling. This composite system should be evaluated independently for each manufacturer's pipe system. Designers should obtain the required mechanical properties directly from the pipe manufacturer to determine fill heights.

**12.7.2.2—Thrust**

The factored thrust, $T_L$, per unit length of wall shall be taken as:

$$T_L = \frac{P_{FD}(S)}{2} + \frac{P_{FL}(C_L)F_1}{2} \qquad (12.7.2.2\text{-}1)$$

in which:

$$C_L = \ell_w \le S \qquad (12.7.2.2\text{-}2)$$

- for corrugated metal pipe:

$$F_1 = \frac{0.75S}{\ell_w} \ge F_{\min} \qquad (12.7.2.2\text{-}3)$$

$$F_{\min} = \frac{15}{12(S)} \ge 1 \qquad (12.7.2.2\text{-}4)$$

- for long-span corrugated metal structures:

$$F_1 = \frac{0.54(S)}{\frac{w_t}{12} + LLDF(H) + 0.03(S)} \qquad (12.7.2.2\text{-}5)$$

where:

$C_L$ = width of culvert on which live load is applied parallel to span (ft)
$LLDF$ = live load distribution factor as specified in Article 3.6.1.2.6
$\ell_w$ = live load patch length at depth $H$ as specified in Article 3.6.1.2.6
$P_{FD}$ = factored dead load vertical crown pressure as specified in Article 12.12.3.4 with $VAF$ taken as 1.0 and $D_o$ taken as $S$ (ksf)

**C12.7.2.2**

Factored vertical crown pressure is calculated as the factored free-field soil pressure at the elevation of the top of the structure, plus the factored live load pressure distributed through the soil cover to the top of the structure.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$P_{FL}$ = factored live load vertical crown pressure as specified in Article 12.12.3.4 (ksf)
$S$ = culvert span (ft)
$T_L$ = factored thrust per unit length (kip/ft)
$w_t$ = tire patch width as specified in Article 3.6.1.2.5 (in.)

**12.7.2.3—Wall Resistance**

The factored axial resistance, $R_n$, per unit length of wall, without consideration of buckling, shall be taken as:

$$R_n = \phi F_y A \qquad (12.7.2.3\text{-}1)$$

where:

$A$ = wall area (in.$^2$/ft)
$F_y$ = yield strength of metal (ksi)
$\phi$ = resistance factor as specified in Article 12.5.5

**12.7.2.4—Resistance to Buckling**

The wall area, calculated using Eq. 12.7.2.3-1, shall be investigated for buckling. If $f_{cr} < F_y$, $A$ shall be recalculated using $f_{cr}$ in lieu of $F_y$.

$$\text{If } S < \left(\frac{r}{k}\right)\sqrt{\frac{24E_m}{F_u}}\text{, then } f_{cr} = F_u - \frac{\left(\frac{F_u kS}{r}\right)^2}{48E_m} \qquad (12.7.2.4\text{-}1)$$

$$\text{If } S > \left(\frac{r}{k}\right)\sqrt{\frac{24E_m}{F_u}}\text{, then } f_{cr} = \frac{12E_m}{\left(\frac{kS}{r}\right)^2} \qquad (12.7.2.4\text{-}2)$$

where:

$S$ = diameter of pipe or span of plate structure (in.)
$E_m$ = modulus of elasticity of metal (ksi)
$F_u$ = tensile strength of metal (ksi)
$f_{cr}$ = critical buckling stress (ksi)
$r$ = radius of gyration of corrugation (in.)
$k$ = soil stiffness factor taken as 0.22

*12.7.2.4.1—Critical Compressive Stress*

For steel-reinforced thermoplastic culvert, stub compression test (AASHTO T 341) data shall be provided to establish the $f_{cr}$ of the wall profile being evaluated. If $f_{cr}$ value is less than the value established by Article 12.7.2.4, it shall be used as the limiting critical compressive stress for the pipe wall.

**C12.7.2.4**

The use of 0.22 for the soil stiffness is thought to be conservative for the types of backfill material allowed for pipe and arch structures. This lower bound on soil stiffness has a long history of use in previous editions of the Standard Specifications.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.7.2.5—Seam Resistance

For pipe fabricated with longitudinal seams, the factored resistance of the seam shall be sufficient to develop the factored thrust in the pipe wall, $T_L$.

### 12.7.2.6—Handling and Installation Requirements

Handling flexibility shall be indicated by a flexibility factor determined as:

$$FF = \frac{S^2}{E_m I} \qquad (12.7.2.6\text{-}1)$$

Values of the flexibility factors for handling and installation shall not exceed the values for steel and aluminum pipe and plate pipe structures as specified in Article 12.5.6.

**C12.7.2.6**

Transverse stiffeners may be used to assist corrugated structural plate structures to meet flexibility factor requirements.

### 12.7.2.7—Profile Evaluation for Steel-Reinforced Thermoplastic Culverts

To assure the adequacy of the thermoplastic liner, the culvert manufacturer shall provide the results of a three-dimensional finite element analysis of the profile that has been calibrated against results of full-scale tests. A minimum of two full-scale tests are required to properly calibrate the results of the finite element analysis. In particular, the measurement and prediction of the maximum strains within the profile shall be identified. The predicted long-term tensile strains within the profile shall be within the allowable limits for the HDPE material being used in the profile. The strain limits for polyethylene materials shall be taken as specified in Table 12.12.3.3-1.

Additionally, in order to establish the relative long-term interaction of the steel reinforcement with the HDPE profile, the stub compression test (AASHTO T 341) shall be performed utilizing stroke rates of 0.05 in./minute, 0.005 in./minute, and 0.0005 in./minute and the results compiled to determine if a reduction in the HDPE modulus results in a reduced result from the stub compression tests. If a reduction factor is deemed to be appropriate, the reduced value shall be used as described in Article 12.7.2.4.1.

**C12.7.2.7**

The full-scale tests should follow the loading conditions, measurements, and test methods consistent with those utilized in the research report *DuroMaxx Pipe Assessment* by I. D. Moore (24 in. – February 2009, 60 in. – August 2009) or similar approved method.

While the steel ribs or corrugations are the main load-carrying member of the culvert, the thermoplastic profile braces the steel ribs or corrugations from distortion or buckling under load and is critical to the pipe performance. The liner also serves to distribute the load between ribs or corrugations. A structural evaluation of the profile alone is not required. However, an evaluation of the composite system of thermoplastic liner and steel rib or corrugation is necessary. It is important to assure that the tensile strains within the profile do not exceed the long-term strain capacity for the thermoplastic material used in the construction of the pipe.

### 12.7.3—Smooth Lined Pipe

Corrugated metal pipe composed of a smooth liner and corrugated shell attached integrally at helical seams, spaced not more than 30.0 in. apart, may be designed on the same basis as a standard corrugated metal pipe having the same corrugations as the shell and a weight per ft not less than the sum of the weights per ft of liner and helically corrugated shell.

The pitch of corrugations shall not exceed 3.0 in., and the thickness of the shell shall not be less than 60 percent of the total thickness of the equivalent standard pipe.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.7.4—Stiffening Elements for Structural Plate Structures

The stiffness and flexural resistance of structural plate structures may be increased by adding circumferential stiffening elements to the crown. Stiffening elements shall be symmetrical and shall span from a point below the quarter-point on one side of the structure, across the crown, and to the corresponding point on the opposite side of the structure.

**C12.7.4**

Acceptable stiffening elements are:

- Continuous longitudinal structural stiffeners connected to the corrugated plates at each side of the top arc: metal or reinforced concrete, either singly or in combination; and
- Reinforcing ribs formed from structural shapes, curved to conform to the curvature of the plates, fastened to the structure to ensure integral action with the corrugated plates, and spaced at such intervals as necessary.

### 12.7.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26, "Metal Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.8—LONG-SPAN STRUCTURAL PLATE STRUCTURES

### 12.8.1—General

The provisions herein and in Article 12.7 shall apply to the structural design of buried long-span structural plate corrugated metal structures.

The following shapes, illustrated in Figure 12.8.1-1, shall be considered long-span structural plate structures:

- Structural plate pipe and arch shaped structures that require the use of special features specified in Article 12.8.3.5, and
- Special shapes of any size having a radius of curvature greater than 13.0 ft in the crown or side plates. Metal box culverts are not considered long-span structures and are covered in Article 12.9.

**C12.8.1**

These structures become part of a composite system comprised of the metal structure section and the soil envelope, both of which contribute to the behavior of the system.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

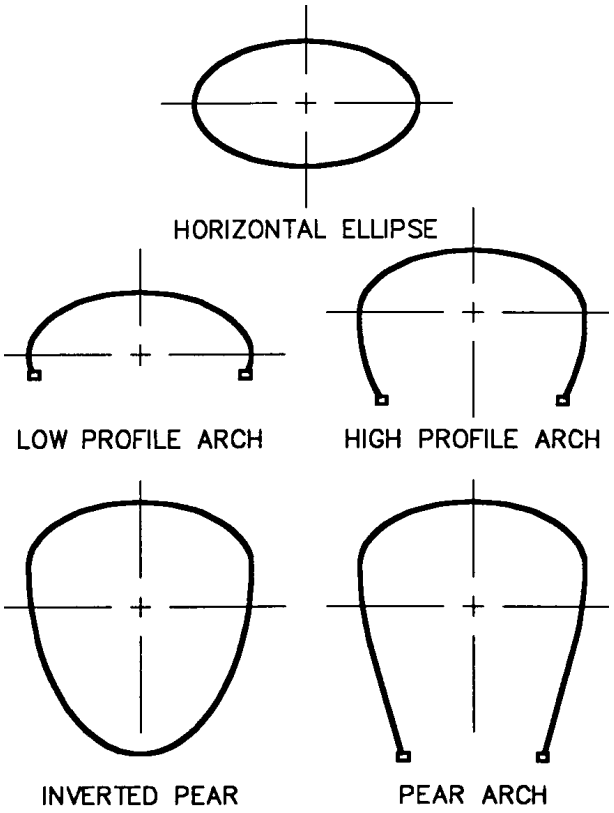

**Figure 12.8.1-1—Long-Span Shapes**

### 12.8.2—Service Limit State

No service limit state criteria need be required.

### C12.8.2

Soil design and placement requirements for long-span structures are intended to limit structure deflections. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction.

### 12.8.3—Safety Against Structural Failure

With the exception of the requirements for buckling and flexibility, the provisions of Article 12.7 shall apply, except as described herein.

Dimensions and properties of structure cross-sections, minimum seam strength, mechanical and chemical requirements, and bolt properties for long-span structural plate sections shall be taken as specified in Appendix A12 or as described herein.

### C12.8.3

Most long-span culverts are designed for a larger load factor; however, the limit states of flexure and buckling are ignored for those structures. Considering these limit states reduces the uncertainty in the final design and permits use of a lower load factor. This is the same approach used for metal box culverts.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.8.3.1—Section Properties

*12.8.3.1.1—Cross-Section*

The provisions of Article 12.7 shall apply, except as specified.

Structures not described herein shall be regarded as special designs.

Table A12-3 shall apply. Minimum requirements for section properties shall be taken as specified in Table 12.8.3.1.1-1. Covers that are less than that shown in Table 12.8.3.1.1-1 and that correspond to the minimum plate thickness for a given radius may be used if ribs are used to stiffen the plate. If ribs are used, the plate thickness may not be reduced below the minimum shown for that radius, and the moment of inertia of the rib and plate section shall not be less than that of the thicker unstiffened plate corresponding to the fill height. Use of soil cover less than the minimum values shown for a given radius shall require a special design.

Designs not covered in Table 12.8.3.1.1-1 should not be permitted unless substantiated by documentation acceptable to the Owner.

*C12.8.3.1.1*

Sharp radii generate high soil pressures. Avoid high ratios when significant heights of fill are involved.

**Table 12.8.3.1.1-1—Minimum Requirements for Long-Span Structures with Acceptable Special Features**

| Top Arc Minimum Thickness (in.) | | | | | |
|---|---|---|---|---|---|
| Top Radius (ft) | ≤15.0 | 15.0–17.0 | 17.0–20.0 | 20.0–23.0 | 23.0–25.0 |
| 6 in. × 2 in. Corrugated Steel Plate—Top Arc Minimum Thickness (in.) | 0.111 | 0.140 | 0.170 | 0.218 | 0.249 |
| Geometric Limits | | | | | |
| The following geometric limits shall apply:<br>• Maximum plate radius—25.0 ft<br>• Maximum central angle of top arc—80.0 degrees<br>• Minimum ratio, top arc radius to side arc radius—2<br>• Maximum ratio, top arc radius to side arc radius—5 | | | | | |
| Minimum Cover (ft) | | | | | |
| Top Radius (ft) | ≤ 15.0 | 15.0–17.0 | 17.0–20.0 | 20.0–23.0 | 23.0–25.0 |
| Steel thickness without ribs (in.) | | | | | |
| 0.111 | 2.5 | — | — | — | — |
| 0.140 | 2.5 | 3.0 | — | — | — |
| 0.170 | 2.5 | 3.0 | 3.0 | — | — |
| 0.188 | 2.5 | 3.0 | 3.0 | — | — |
| 0.218 | 2.0 | 2.5 | 2.5 | 3.0 | — |
| 0.249 | 2.0 | 2.0 | 2.5 | 3.0 | 4.0 |
| 0.280 | 2.0 | 2.0 | 2.5 | 3.0 | 4.0 |

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*12.8.3.1.2—Shape Control*

The requirements of Articles 12.7.2.4 and 12.7.2.6 shall not apply for the design of long-span structural plate structures.

*12.8.3.1.3—Mechanical and Chemical Requirements*

Tables A12-3, A12-8, and A12-10 shall apply.

**12.8.3.2—Thrust**

The factored thrust in the wall shall be determined by Eq. 12.7.2.2-1, except the value of $S$ in the Equation shall be replaced by twice the value of the top arc radius, $R_T$.

**12.8.3.3—Wall Area**

The provisions of Article 12.7.2.3 shall apply.

**12.8.3.4—Seam Strength**

The provisions of Article 12.7.2.5 shall apply.

**12.8.3.5—Acceptable Special Features**

*12.8.3.5.1—Continuous Longitudinal Stiffeners*

Continuous longitudinal stiffeners shall be connected to the corrugated plates at each side of the top arc. Stiffeners may be metal or reinforced concrete either singly or in combination.

*12.8.3.5.2—Reinforcing Ribs*

Reinforcing ribs formed from structural shapes may be used to stiffen plate structures. Where used, they should be:

- curved to conform to the curvature of the plates,
- fastened to the structure as required to ensure integral action with the corrugated plates, and
- spaced at such intervals as necessary to increase the moment of inertia of the section to that required for design.

**12.8.4—Safety Against Structural Failure—Foundation Design**

**12.8.4.1—Settlement Limits**

**C12.8.4.1**

A geotechnical survey of the site shall be made to determine that site conditions will satisfy the requirement that both the structure and the critical backfill zone on each side of the structure be properly supported. Design shall satisfy the requirements of Article 12.6.2.2, with the following factors to be considered when establishing settlement criteria:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Once the structure has been backfilled over the crown, settlement of the supporting backfill relative to the structure must be limited to control downdrag forces. If the sidefill will settle more than the structure, a detailed analysis may be required.

- Settlement along the longitudinal centerline of arch structures must be limited to maintain slope and preclude footing cracks in arches.

Calculated differential settlement across the structure taken from springline-to-springline, Δ, shall satisfy:

$$\Delta \le \frac{0.01S^2}{R} \qquad (12.8.4.1\text{-}1)$$

where:

$S$ = span of structure between springlines of long-span structural plate structures (ft)
$R$ = rise of structure (ft)

More restrictive settlement limits may be required where needed to protect pavements or to limit longitudinal differential deflections.

Once the top arc of the structure has been backfilled, downdrag forces may occur if the structure backfill settles into the foundation more than the structure. This results in the structure carrying more soil load than the overburden directly above it. If undertaken prior to erecting the structure, site improvements such as surcharging, foundation compacting, etc., often adequately correct these conditions.

Where the structure will settle uniformly with the adjacent soils, long-spans with full inverts can be built on a camber to achieve a proper final grade.

For design, differential settlement between the footings taken across the structure is limited to avoid excessive eccentricity. The limit on any settlement-induced rotation of the structure maintains the top arc centerline within one percent of span, as shown in Figure C12.8.4.1-1.

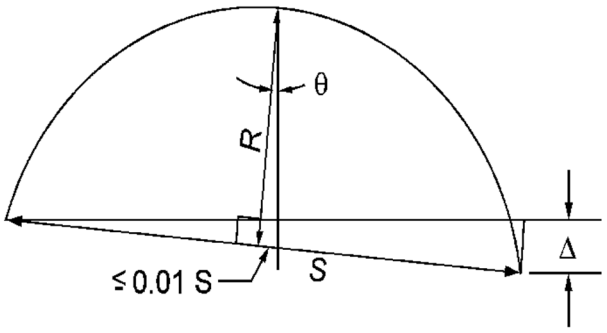

**Figure C12.8.4.1-1—Differential Settlement**

The rotation of the structure, θ, may be determined as:

$$\theta = \tan^{-1}\left(\frac{\Delta}{S}\right) \qquad (C12.8.4.1\text{-}1)$$

### 12.8.4.2—Footing Reactions in Arch Structures

Footing reactions may be taken as:

$$R_V = \left(V_{DL} + V_{LL}\right)\cos\Delta \qquad (12.8.4.2\text{-}1)$$

$$R_H = \left(V_{DL} + V_{LL}\right)\sin\Delta \qquad (12.8.4.2\text{-}2)$$

in which:

$V_{DL}$ = $[H_2(S) - A_T]\,\gamma_s/2$
$V_{LL}$ = $n(A_L)/(8 + 2\,H_1)$
$n$ = integer $(2H_1/L_w + 2) \le$ number of adjoining traffic lanes

where:

$R_V$ = vertical footing reaction component (kip/ft)
$R_H$ = horizontal footing reaction component (kip/ft)
Δ = return angle of the structure (degrees)

### C12.8.4.2

Footing reactions are calculated by simple statics to support the vertical loads. Soil load footing reactions ($V_{DL}$) are taken as the weight of the fill and pavement above the springline of the structure. Where footings extend out beyond the springline and the foundation has not previously carried the design overburden, this additional soil load ($E_v$) may need to be added to $V_{DL}$ in an embankment installation.

Live loads that provide relatively limited pressure zones acting on the crown of the structure may be distributed to the footings as indicated in Figure C12.8.4.2-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$A_L$ = axle load (kip), taken as 50 percent of all axle loads that can be placed on the structure at one time, i.e.:

- 32.0 kip for the design truck axle
- 50.0 kip for the design tandem axle pair
- 160.0 kip for E80 railroad loading

$A_T$ = area of the top portion of the structure above the springline ($ft^2$)
$H_1$ = height of cover above the footing to traffic surface (ft)
$H_2$ = height of cover from the springline of the structure to traffic surface (ft)
$L_w$ = lane width (ft)
$\gamma_s$ = unit weight of soil (kcf)
$S$ = span (ft)

The distribution of live load through the fill shall be based on any accepted methods of analysis.

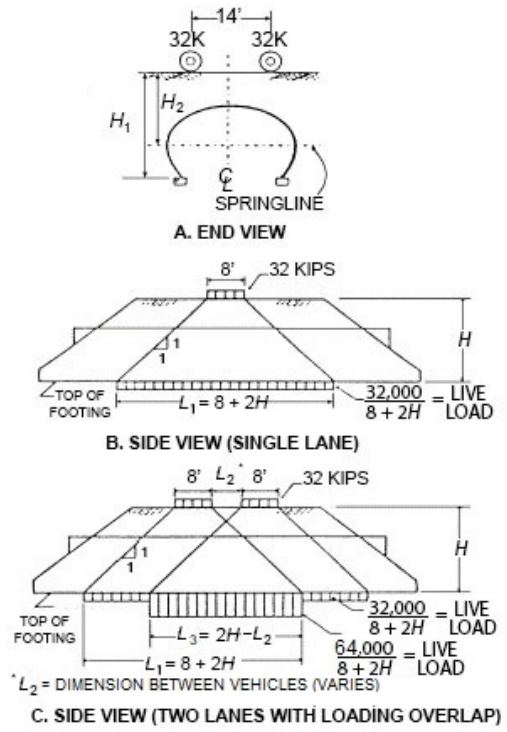

**Figure C12.8.4.2-1—Live-Load Footing Reaction Due to Axles of the Design Truck, per Footing**

### 12.8.4.3—Footing Design

Reinforced concrete footings shall be designed in accordance with Article 10.6 and shall be proportioned to satisfy settlement requirements of Article 12.8.4.1.

## 12.8.5—Safety Against Structural Failure—Soil Envelope Design

### 12.8.5.1—General

Structural backfill material in the envelope around the structure shall satisfy the requirements of Article 12.4.1.3 for long-span structures. The width of the envelope on each side of the structure shall be proportioned to limit shape change during construction activities outside the envelope and to control deflections at the service limit state.

### C12.8.5.1

Structure erection, backfill, and construction shall meet all the requirements of Section 26 of the *AASHTO LRFD Bridge Construction Specifications*. The performance of the structure depends upon the in-situ embankment or other fill materials beyond the structural backfill. Design must consider the performance of all materials within the zone affected by the structure.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.8.5.2—Construction Requirements

The structural backfill envelope shall either extend to the trench wall and be compacted against it or extend a distance adequate to protect the shape of the structure from construction loads. The remaining trench width may be filled with suitable backfill material compacted to satisfy the requirements of Article 12.8.5.3. In embankment conditions, the minimum structural backfill width shall be taken as 6.0 ft. Where dissimilar materials not meeting geotechnical filter criteria are used adjacent to each other, a suitable geotextile shall be provided to avoid migration.

### C12.8.5.2

The purpose of this provision is to control shape change from construction activities outside the envelope in trench conditions.

### 12.8.5.3—Service Requirements

The width of the envelope on each side of the structure shall be adequate to limit horizontal compression strain to one percent of the structure's span on each side of the structure.

Determination of the horizontal compressive strain shall be based on an evaluation of the width and quality of the structural backfill material selected as well as the in-situ embankment or other fill materials within the zone on each side of the structure taken to extend to a distance equal to the rise of the structure, plus its cover height as indicated in Figure 12.8.5.3-1.

Forces acting radially off the small radius corner arc of the structure at a distance, $d_1$, from the structure may be taken as:

$$P_1 = \frac{T}{R_c + d_1} \tag{12.8.5.3-1}$$

where:

$P_1$ = horizontal pressure from the structure at a distance, $d_1$ (ksf)
$d_1$ = distance from the structure (ft)
$T$ = total dead load and live load thrust in the structure (Article 12.8.3.2) (kip/ft)
$R_c$ = corner radius of the structure (ft)

The required envelope width adjacent to the pipe, $d$, may be taken as:

$$d = \frac{T}{P_{Brg}} - R_c \tag{12.8.5.3-2}$$

where:

$d$ = required envelope width adjacent to the structure (ft)
$P_{Brg}$ = allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf)

### C12.8.5.3

The purpose of this provision is to limit deflections under service loads. The limit on soil compression limits the theoretical design increase in span to two percent. This is a design limit, not a performance limit. Any span increase that occurs is principally due to the consolidation of the side support materials as the structure is loaded during backfilling. These are construction movements that attenuate when full cover is reached.

Eqs. 12.8.5.3-1 and 12.8.5.3-2 conservatively assume that the pressure from the structure acts radially outward from the corner arc without further dissipation. Figure C12.8.5.3-1 provides the geometric basis of these Equations.

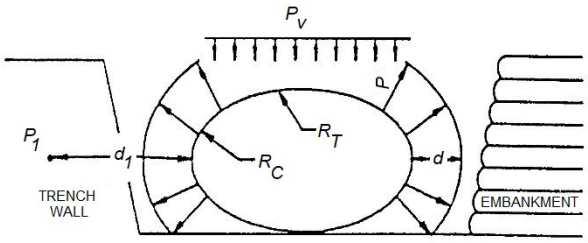

**Figure C12.8.5.3-1—Radial Pressure Diagram**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The structural backfill envelope shall be taken to continue above the crown to the lesser of:

- the minimum cover level specified for that structure,
- the bottom of the pavement or granular base course where a base course is present below the pavement, or
- the bottom of any relief slab or similar construction where one is present.

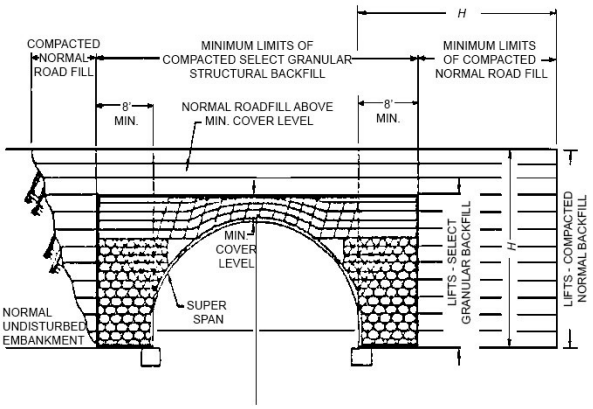

**Figure 12.8.5.3-1—Typical Structural Backfill Envelope and Zone of Structure Influence**

## 12.8.6—Safety Against Structural Failure—End Treatment Design

### 12.8.6.1—General

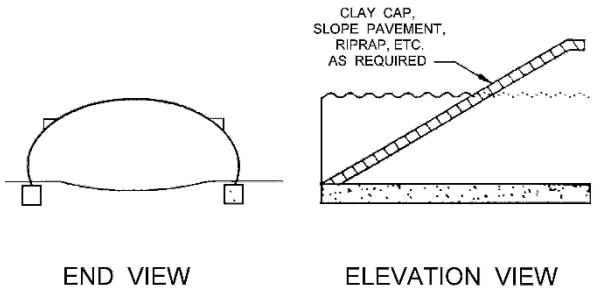
End treatment selection and design shall be considered as an integral part of the structural design.

### C12.8.6.1

Proper end treatment design ensures proper support of the ends of the structure while providing protection from scour, hydraulic uplift, and loss of backfill due to erosion forces.

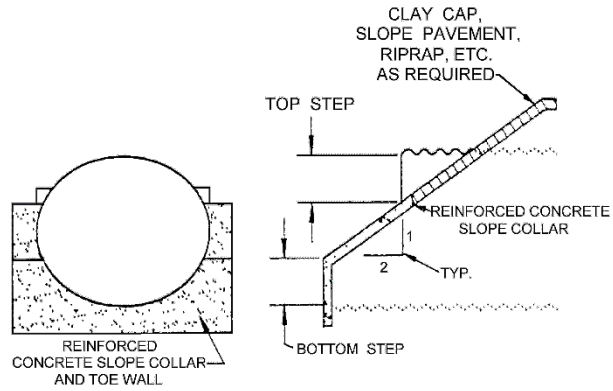
### 12.8.6.2—Standard Shell End Types

The standard end types for the corrugated plate shell shall be taken to be those shown in Figure 12.8.6.2-1.



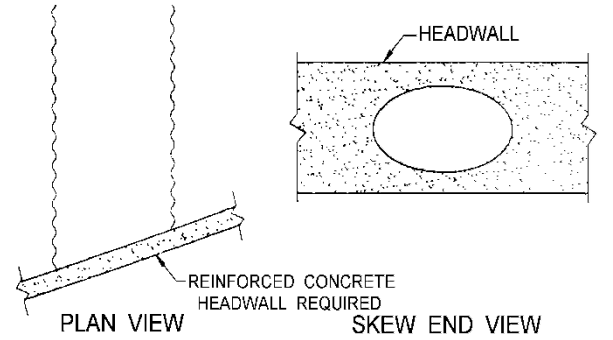
### C12.8.6.2

Standard end types refer to the way the structural plate structure's ends are cut to match the fill slope, stream banks, etc. While the type of end selected may have aesthetic or hydraulic considerations, the structural design must ensure adequate structural strength and protection from erosion. Hydraulic considerations may require wingwalls, etc.



Step bevel, full bevel, and skewed ends all involve cutting the plates within a ring. Each has its own structural considerations.

The square end is the simplest arrangement. No plates are cut and the barrel retains its integrity.



© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

(A) SQUARE END

(B) STEP BEVEL

(C) SKEW CUT END
(REQUIRES FULL HEADWALL)

**Figure 12.8.6.2-1—Standard Structure End Types**

The following considerations shall apply to step bevels:

- The rise of the top step shall be equal to or greater than the rise of the top arc, i.e., plates in the top arc are left uncut.

Step bevels cut the corner (and side on pear and high profile arch shapes) plates on a diagonal (bevel) to match the fill slope.

Step bevels are widely used. The plates in the large radius top arc are left uncut to support the sides of the structure near each end.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- For structures with inverts, the bottom step shall satisfy the requirements for a top step.
- For arches, the bottom step shall be a minimum of 6.0 in. high.
- The slope of the cut plates generally should be no flatter than 3:1.
- The upper edge of the cut plates shall be bolted to and supported by a structural concrete slope collar, slope pavement, or similar device.

Full bevel ends shall be used in special designs only. Structures with full inverts shall have a bottom step conforming to the requirements for step bevel ends.

The bevel cut edge of all plates shall be supported by a suitable, rigid concrete slope collar.

Skew cut ends shall be fully connected to and supported by a headwall of reinforced concrete or other rigid construction. The headwall shall extend an adequate distance above the crown of the structure to be capable of reacting the ring compression thrust forces from the cut plates. In addition to normal active earth and live load pressures, the headwall shall be designed to react a component of the radial pressure exerted by the structure as specified in Article 12.8.5.

Invert plates must be left uncut to avoid leaving the invert as triangular shaped elements, when viewed in plan, running upstream and downstream.

Diagonally-cut corner and side plates become a retaining wall, supporting the fill slope beside them. They must be provided with suitable, rigid support at the top that acts as a top wale beam and be limited in length. These plates have limited longitudinal strength and inadequate bending strength or fixity to act as a cantilevered retaining wall.

When a full bevel cuts the top plates, additional support is necessary to backfill the structure. Typically, the top step is left in place and field cut only after a suitable rigid concrete slope collar has been poured and adequately cured.

Ring compressive thrust forces act circumferentially around the structure following the corrugations. At the skew cut ends of the plate, these forces act tangentially to the plate and must be resisted by a headwall. Additionally, because a skew cut structure is not perpendicular to the headwall, a portion of the radial pressure from the structure acts normal to the back of the headwall.

#### 12.8.6.3—Balanced Support

Designs and details shall provide soil support that is relatively balanced from side to side, perpendicularly across the structure. In lieu of a special design, slopes running perpendicularly across the structure shall not exceed ten percent for cover heights of 10.0 ft or less and 15 percent for higher covers.

When a structure is skewed to an embankment, the fill shall be detailed to be warped to maintain balanced support and to provide an adequate width of backfill and embankment soil to support the ends.

#### C12.8.6.3

Flexible structures have relatively low bending strength. If the earth support is not balanced, the structure in effect becomes a retaining wall. An excessive imbalance causes shape distortion and ultimately failure.

When a structure is skewed to an embankment, two diagonally opposite areas at the ends of the structure are not adequately supported. This must be corrected by extending the embankment an adequate distance out beside the structure.

In lieu of a special design, details provided in Article C12.6.8.2 may be considered.

A properly warped embankment is characterized by equal elevation topographical lines crossing the structure perpendicularly and extending beyond it a suitable distance so that the volume of earth included in the warp provides a gravity retaining wall capable of supporting the radial pressures from the structure with adequate safety.

#### 12.8.6.4—Hydraulic Protection

*12.8.6.4.1—General*

In hydraulic applications, provisions shall be made to protect the structure, taken to include the shell, footings, structural backfill envelope, and other fill materials within the zone influenced by the structure.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*12.8.6.4.2—Backfill Protection*

Design or selection of backfill gradation shall include consideration of loss of backfill integrity due to piping. If materials prone to piping are used, the structure and ends of the backfill envelope shall be adequately sealed to control soil migration, infiltration, or both.

*C12.8.6.4.2*

Backfill piping and migration is always a major consideration in selecting its specific gradation. The ends of the backfill envelope may be sealed using one or a combination of a compacted clay cap, concrete slope pavements, grouted riprap, headwalls to the design storm elevation, and similar details.

*12.8.6.4.3—Cut-Off (Toe) Walls*

All hydraulic structures with full inverts shall be designed and detailed with upstream and downstream cut-off walls. Invert plates shall be bolted to cut-off walls at a maximum 20.0-in. center-to-center spacing using 0.75-in. bolts.

The cut-off wall shall extend to an adequate depth to limit hydraulic percolation to control uplift forces as specified in Article 12.8.6.4.4 and scour as specified in Article 12.8.6.4.5.

*12.8.6.4.4—Hydraulic Uplift*

Hydraulic uplift shall be considered for hydraulic structures with full inverts where the design flow level in the pipe can drop quickly. The design shall provide means to limit the resulting hydraulic gradients, with the water level higher in the backfill than in the pipe, so that the invert will not buckle and the structure will not float. Buckling may be evaluated as specified in Article 12.7.2.4, with the span of the structure taken as twice the invert radius.

*C12.8.6.4.4*

Structural plate structures are not watertight and allow for both infiltration and exfiltration through the structure's seams, bolt holes, and other discontinuities. Where uplift can be a concern, designs typically employ adequate cut-off walls and other means to seal off water flow into the structural backfill.

*12.8.6.4.5—Scour*

Scour design shall satisfy the requirements of Article 12.6.5. Where erodible soils are encountered, conventional means of scour protection may be employed to satisfy these requirements.

Deep foundations such as piles or caissons should not be used unless a special design is provided to consider differential settlement and the inability of intermittent supports to retain the structural backfill if scour proceeds below the pile cap.

*C12.8.6.4.5*

Structures with full inverts eliminate footing scour considerations when adequate cut-off walls are used. For arches, reinforced concrete invert pavements, riprap, grouted riprap, etc., can be employed to provide scour protection.

**12.8.7—Concrete Relieving Slabs**

Concrete relieving slabs may be used to reduce moments in long-span structures.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the span of the structure. The relieving slab shall extend across the width subject to vehicular loading, and its depth shall be determined as specified in Article 12.9.4.6.

**C12.8.7**

Application of a typical concrete relieving slab is shown in Figure 12.9.4.6-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.8.8—Construction and Installation

The construction documents shall require that construction and installation conform to Section 26 of the *AASHTO LRFD Bridge Construction Specifications*.

### 12.8.9—Deep Corrugated Structural Plate Structures

#### 12.8.9.1—General

The provisions of this Section shall apply to the structural design of buried, deep corrugated structural plate. These structures are designed as long-span culverts but must also meet provisions for flexure and general buckling. These structures may be manufactured in multiple shapes. Flexibility criteria and special features are not applicable to deep corrugated structures. The rise to span limit of 0.3 in Article 12.7.1 does not apply.

**C12.8.9.1**

The design of long-span metal structures in these Specifications is currently completed with empirical procedures that limit the shapes and plate thicknesses for the structures and require special features. If the provisions are met, then no design is required for flexure or buckling. NCHRP Report 473 recommended updating design provisions for long-span structures and included provisions to allow structures outside the current limits for long-span structures but included limit states for flexure and general buckling. Article 12.8.9 provides a design procedure for such structures. The provisions of Article 12.8.9 apply to structures fabricated from deep corrugated plate, defined in Article 12.2 as corrugated plate with a corrugation depth greater than 5.0 in.

#### 12.8.9.2—Width of Structural Backfill

##### *12.8.9.2.1—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius ≤5*

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius ≤5 shall extend to at least the minimum cover height above the crown. At the sides of the structure, the minimum extent of the structural backfill from the outside of the structure springline shall meet one of the following:

- Structure constructed in a trench in which the natural soil is at least as stiff as the engineered soil: 8.0 ft or
- Structure constructed in an embankment or in a trench in which the natural soil is less stiff than the engineered soil: one-third of the structure span but not less than 10.0 ft or more than 17.0 ft

but not less than required by culvert–soil interaction analysis.

##### *12.8.9.2.2—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius >5*

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius >5 shall extend to at least the minimum cover height above the crown. At the sides of the structure, the minimum extent of structural backfill shall meet one of the following:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- for structures with spans up to and including 25.0 ft 5.0 in. and less than 5.0 ft of cover: a minimum of 3.5 ft beyond the widest part of the structure, or
- for structures with spans up to and including 25.0 ft 5.0 in. and greater than 5.0 ft of cover and for structures with spans greater than 25.0 ft 5.0 in. at all depths of fill: a minimum of one-fifth of the structure span beyond the widest part of the structure but not less than 5.0 ft nor more than 17.0 ft.

but not less than required by culvert–soil interaction analysis.

**12.8.9.3—Safety Against Structural Failure**

Deep corrugated structures shall be designed in accordance with the provisions of Articles 12.8.1 to 12.8.8, except for modified or additional provisions as follow.

*12.8.9.3.1—Structural Plate Requirements*

Deep corrugated structural plate used to manufacture structures designed under this section shall meet the requirements of AASHTO M 167M/M 167.

Sections may be stiffened. If stiffening is provided by ribs, the ribs shall be bolted to the structural plate corrugation prior to backfilling using a bolt spacing of not more than 16.0 in. for 15.0 by 5.5 in. and 16.0 by 6.0 in. corrugations, or 20.0 in. for 20.0 by 9.5 in. corrugations. The cross-section properties in Table A12-14 shall apply.

*C12.8.9.3.1*

It is acceptable to measure bolt spacing either at the centroid or crest of the structural plate corrugation.

*12.8.9.3.2—Structural Analysis*

Structures designed under the provisions of this Article shall be analyzed by accepted finite element analysis methods that consider both the strength and stiffness properties of the structural plate and the soil. The analysis shall produce thrust and moments for use in design. The analysis must consider all applicable combinations of construction, earth, live, and other applicable load conditions. Springline thrust due to earth load used in wall resistance, buckling, and seam resistance design shall not be less than 1.3 times the earth load thrust computed in accordance with Article 12.7.2.2.

*C12.8.9.3.2*

The computer program CANDE was developed by the FHWA specifically for the design of buried culverts and has the necessary soil and culvert material models to complete designs.

Because distribution of live loads to all long-span culverts does not consider arching, application of the 1.3 factor should be limited to just the earth load component of Article 12.7.2.2.

**12.8.9.4—Minimum Depth of Fill**

For deep corrugated structural plate structures, the minimum depth of cover ($H_D$) shall be the smaller of 3.0 ft or the limits for long-span structural plate structures based on top radius and plate thickness in Table 12.8.3.1.1-1. For deep corrugated structures with the ratio of crown radius to haunch radius >5, minimum cover shall be 1.5 ft for spans ≤25.0 ft 5.0 in. and 2.0 ft for spans >25.0 ft 5.0 in. The minimum depth of cover in all cases shall not

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

be less than that required by culvert–soil interaction analysis.

### 12.8.9.5—Combined Thrust and Moment

The combined effects of moment and thrust at all stages of construction shall meet the following requirement:

$$\left(\frac{T_f}{R_t}\right)^2 + \left|\frac{M_u}{M_n}\right| \le 1.00 \qquad (12.8.9.5\text{-}1)$$

where:

$T_f$ = factored thrust
$R_t$ = factored thrust resistance = $\phi_h F_y A$
$M_u$ = factored applied moment
$M_n$ = factored moment resistance = $\phi_h M_p$
$M_p$ = plastic moment capacity of section

### C12.8.9.5

The equation for combined moment and thrust is taken from the provision for buried structures in the Canadian Highway Bridge Design Code CSA-S6-06. The equation is more liberal than the AASHTO equations for combined moment and thrust (axial force) for steel structures in Article 12.8.9.6. However, the provisions in Article 12.8.9.6 are based on strong axis bending of wide flange sections. The equation for combined moment and thrust is taken from the provision for buried structures in the Canadian Highway Bridge Design Code CSA-S6-06. The equation is more liberal than the AASHTO equations for combined moment and thrust (axial force) for steel structures in Article 6.9.2.2. However, the provisions in Article 6.9.2.2 are based on strong axis bending of wide flange sections.

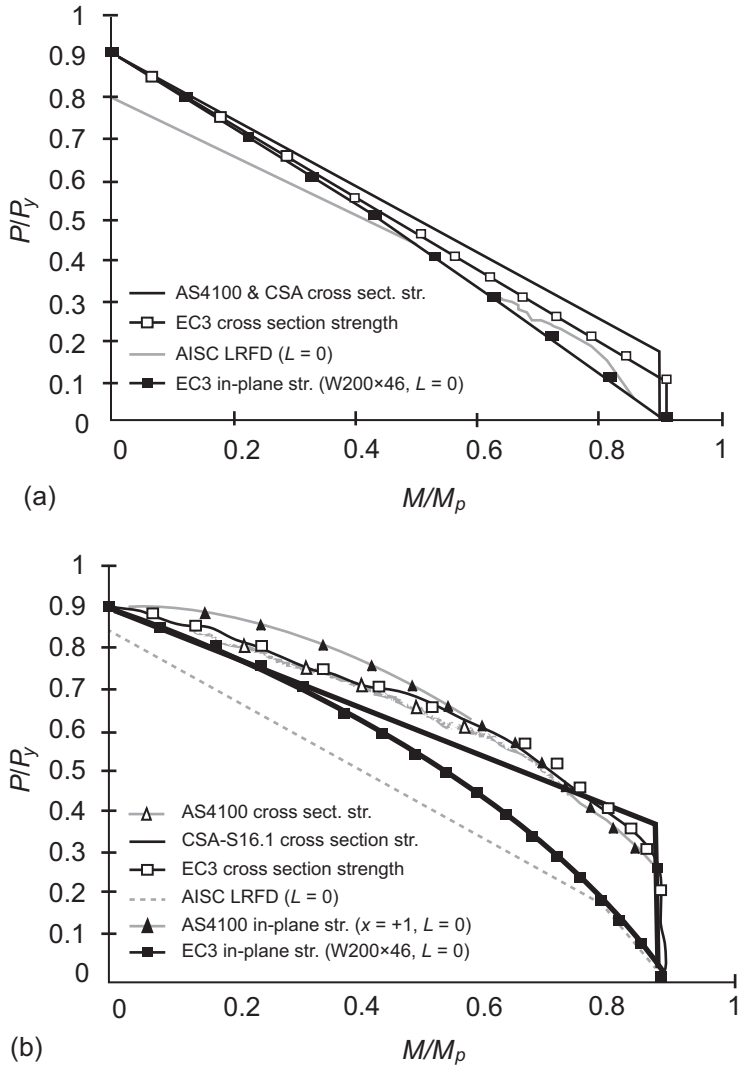


**Figure C12.8.9.5-1—Strength Curves for Member of Zero Length: (a) Strong-Axis; (b) Weak-Axis from White and Clark (1997)**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.8.9.6—Global Buckling

The factored thrust in the culvert wall under the final installed condition shall not exceed the nominal resistance to general buckling capacity of the culvert, computed as:

$$R_b = 1.2\,\varphi_b\,C_n\,(E_p\,I_p)^{\frac{1}{3}}\,(\varphi_s\,M_s\,K_b)^{\frac{2}{3}}\,R_h \qquad (12.8.9.6\text{-}1)$$

where:

$R_b$ = nominal axial force in culvert wall to cause general buckling
$\phi_b$ = resistance factor for general buckling
$C_n$ = scalar calibration factor to account for some nonlinear effects = 0.55
$E_p$ = modulus of elasticity of pipe wall material (ksi)
$I_p$ = moment of inertia of stiffened culvert wall per unit length, (in.$^4$)
$\phi_s$ = resistance factor for soil
$M_s$ = constrained modulus of embedment computed based on the free field vertical stress at a depth halfway between the top and springline of the structure (Table 12.12.3.5-1)
$K_b$ = $(1-2\nu)/(1-\nu^2)$
$\nu$ = Poisson's ratio of soil
$R_h$ = correction factor for backfill geometry
= $11.4/(11+S/H)$
$S$ = culvert span
$H$ = depth of fill over top of culvert

### C12.8.9.6

The proposed buckling equations are taken from the recommendations of NCHRP Report 473, *Recommended Specifications for Large-Span Culverts*.

Global buckling of deep corrugated structures occurs over a long wavelength; thus, the soil modulus computed at a depth halfway between the top and springline of the structure is representative of the overall soil resistance to buckling.

### 12.8.9.7—Connections

The factored moment resistance of longitudinal connections shall be at least equal to the factored applied moment but not less than the greater of:

- 75 percent of the factored moment resistance of the member or
- the average of the factored applied moment and the factored moment resistance of the member.

Moment resistance of connections may be obtained from qualified tests or published standards.

### C12.8.9.7

The *AASHTO LRFD Bridge Construction Specifications* require longitudinal joints to be staggered to avoid a continuous line of bolts on a structure.

## 12.9—STRUCTURAL PLATE BOX STRUCTURES

### 12.9.1—General

The design method specified herein shall be limited to depth of cover from 1.4 to 5.0 ft.

The provisions of this Article shall apply to the design of structural plate box structures, hereinafter called "metal box culverts." The provisions of Articles 12.7 and 12.8 shall not apply to metal box culvert designs, except as noted.

If rib stiffeners are used to increase the flexural resistance and moment capacity of the plate, the transverse

### C12.9.1

These Specifications are based on three types of data:

- finite element soil–structure interaction analyses,
- field loading tests on instrumented structures, and
- extensive field experience.

Structural plate box culverts are composite-reinforced rib plate structures of approximately

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

stiffeners shall consist of structural steel or aluminum sections curved to fit the structural plates. Ribs shall be bolted to the plates to develop the plastic flexural resistance of the composite section. Spacing between ribs shall not exceed 2.0 ft on the crown and 4.5 ft on the haunch. Rib splices shall develop the plastic flexural resistance required at the location of the splice.

rectangular shape. They are intended for shallow covers and low, wide waterway openings. The shallow covers and extreme shapes of box culverts require special design procedures.

Metal box culverts differ greatly from conventional metal culvert shapes. Metal box culverts are relatively flat at the top and require a large flexural capacity due to extreme geometry and shallow depths of cover of 5.0 ft or less. Analyses over the range of sizes permitted under these Specifications indicate that flexural requirements govern the choice of section in all cases. The effects of thrust are negligible in comparison with those of flexure. This difference in behavior requires a different approach in design.

For information regarding the manufacture of structures and structural components referred to herein, see AASHTO M 167M/M 167 (ASTM A761/A761M) for steel and M 219 (ASTM B746) for aluminum.

### 12.9.2—Loading

For live loads, the provisions of Article 3.6.1 shall apply.

Unit weights for soil backfill, other than 0.12 kcf, may be considered as specified in Article 12.9.4.2.

### C12.9.2

The earth loads for the design procedure described herein are based upon soil backfill having a standard unit weight, $\gamma_s$, of 0.12 kcf.

### 12.9.3—Service Limit State

No service limit state criteria need be applied in the design of box culvert structures.

### C12.9.3

Soil design and placement requirements for box culvert structures can limit structure deflections satisfactorily. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction, in which case no deflection limits should be imposed on the completed structure.

### 12.9.4—Safety Against Structural Failure

#### 12.9.4.1—General

The resistance of corrugated box culverts shall be determined at the strength limit state in accordance with Articles 12.5.3, 12.5.4, and 12.5.5 and the requirements specified herein.

Box culvert sections for which these Articles apply are defined in Figure 12.9.4.1-1 and Table 12.9.4.1-1. Table A12-10 shall apply.

#### C12.9.4.1

Finite element analyses covering the range of metal box culvert shapes described in this Article have shown that flexural requirements govern the design in all cases. Effects of thrust are negligible when combined with flexure.

The structural requirements for metal box culverts are based on the results of finite element analyses and field measurements of in-service box culverts.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

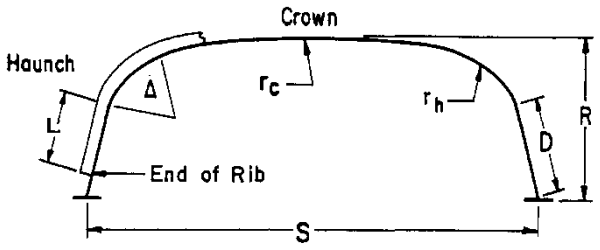

**Figure 12.9.4.1-1—Geometry of Box Culverts**

**Table 12.9.4.1-1—Geometric Requirements for Box Culverts with Spans from 8 ft 9 in. to 25 ft 5 in.**

| |
|---|
| Span, *S*: 8 ft 9 in. to 25 ft 5 in. |
| Rise, *R*: 2 ft 6 in. to 10 ft 6 in. |
| Radius of crown, $r_c \le$ 24 ft 9 $^1/_2$ in. |
| Radius of haunch, $r_h \ge$ 2 ft 6 in. |
| Haunch radius included angle, Δ, 50° to 70° |
| Length of leg, *D,* measured to the bottom of the plate, may vary from 4 $^3/_4$ to 71 in. |
| Minimum length of rib on leg, *L*, least of 19.0 in., (*D* − 3.0) in., or to within 3.0 in. of the top of a concrete footing |

**Table 12.9.4.1-2—Geometric Requirements for Box Culverts with Spans from 25 ft 6 in. to 36 ft 0 in.**

| |
|---|
| Span, *S*: 25 ft 6 in. to 36 ft 0 in. |
| Rise, *R*: 5 ft 7 in. to 14 ft 0 in. |
| Radius of crown, $r_c \le$ 26 ft 4 in. |
| Radius of haunch, $r_h \ge$ 3 ft 8 in. |
| Haunch radius included angle, Δ: 48° to 68° |
| Length of leg, *D*, measured to the bottom of the plate, may vary from 4 $^3/_4$ to 71 in. |
| Minimum length of rib on leg, *L*, least of 28.0 in., (*D* – 3.0) in., or to within 3.0 in. of the top of a concrete footing |

The flexural resistance of corrugated plate box structures shall be determined using the specified yield strength of the corrugated plate.

The flexural resistance of plate box structures with ribbed sections shall be determined using specified yield strength values for both rib and corrugated shell. Computed values may be used for design only after confirmation by representative flexural testing. Rib splices shall develop the plastic moment capacity required at the location of the splice.

### 12.9.4.2—Moments Due to Factored Loads

Unfactored crown and haunch dead and live load moments, $M_{d\ell}$ and $M_{\ell\ell}$, may be taken as:

For spans ≤25.0 ft 5.0 in.:

### C12.9.4.2

The number of "wheels per notional axle group" determines the value of $C_2$ in Table 12.9.4.2-1. The following guidelines are consistent with the development of Table 12.9.4.2-1:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$M_{d\ell} = \gamma_s \left\{ S^3 \left[ 0.0053 - 0.00024(S-12) \right] + 0.053(H-1.4)S^2 \right\} \quad (12.9.4.2\text{-}1)$$

For spans from 25.0 ft 6.0 in. through 36.0 ft 0 in. with a geometry profile that meets $r_c$ = 26.0 ft, $r_h$ = 3.0 ft 8 $^7/_8$ in., and Δ = 49.16 degrees:

$$M_{d\ell} = \lambda_s \begin{cases} S^3 \left[ 0.00194 - 0.0002(S-26)(H-1.1) \right] \\ +(H-1.4)\left[ 0.053S^2 + 0.6(S-26)^2 \right] \end{cases} \quad (12.9.4.2\text{-}2)$$

$$M_{\ell\ell} = C_{\ell\ell} K_1 \frac{S}{K_2} \quad (12.9.4.2\text{-}3)$$

where:

$M_{d\ell}$ = sum of the nominal crown and haunch dead load moments (kip-ft/ft)
$M_{\ell\ell}$ = sum of the nominal crown and haunch live load moments (kip-ft/ft)
$S$ = box culvert span (ft)
$\gamma_s$ = soil unit weight (kcf)
$H$ = height of cover from the box culvert rise to top of pavement (ft)
$C_{\ell\ell}$ = adjusted live load
= $C_1\, C_2\, A_L$ (kip)
$A_L$ = sum of all axle loads in an axle group (kip)
$C_1$ = 1.0 for single axles and 0.5 + $S$/50 ≤ 1.0 for tandem axles
$C_2$ = adjustment factor for number of wheels on a design axle as specified in Table 12.9.4.2-1

in which:

$$K_1 = \frac{0.08}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 8 \le S < 20 \quad (12.9.4.2\text{-}4)$$

$$K_1 = \frac{0.08 - 0.002\,(S-20)}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 20 \le S \le 36 \quad (12.9.4.2\text{-}5)$$

$$K_2 = 0.54H^2 - 0.4H + 5.05, \text{ for } 1.4 \le H < 3.0 \quad (12.9.4.2\text{-}6)$$

$$K_2 = 1.90H + 3, \text{ for } 3.0 \le H \le 5.0 \quad (12.9.4.2\text{-}7)$$

- Use “2” as the number of wheels when the design is based on an axle with two wheels, e.g., two 16.0-kip wheels on one 32.0-kip axle.
- Use “4” as the number of wheels where the design is based on either an axle with four wheels, e.g., two 8.0-kip wheels on each end of a 32.0-kip axle; or two axles with two wheels each, e.g., two 12.5-kip wheels on each of two tandem 25.0-kip axles.
- Use “8” as the number of wheels when the design is based on two axles, each with a pair of wheels at each end of each axle.

For spans from 25.0 ft 6.0 in. through 36.0 ft 0 in. with profiles that do not meet the requirements of Eq. 12.9.4.2-2, finite element modeling that employs soil–structure interaction may be performed to obtain the nominal crown and haunch moments.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**Table 12.9.4.2-1—Adjustment Coefficient Values ($C_2$) for Number of Wheels per Axle**

| Wheels per Notional Axle Group | Cover Depth (ft) | | | |
|---|---|---|---|---|
| | 1.4 | 2.0 | 3.0 | 5.0 |
| 2 | 1.18 | 1.21 | 1.24 | 1.02 |
| 4 | 1.00 | 1.00 | 1.00 | 1.00 |
| 8 | 0.63 | 0.70 | 0.82 | 0.93 |

Unless otherwise specified, the design truck specified in Article 3.6.1.2.2 should be assumed to have four wheels on an axle. The design tandem specified in Article 3.6.1.2.3 should be assumed to be an axle group consisting of two axles with four wheels on each axle.

The factored moments, $M_{d\ell u}$ and $M_{\ell\ell u}$ as referred to in Article 12.9.4.3, shall be determined as specified in Table 3.4.1-1, except that the live load factor used to compute $M_{\ell\ell u}$ shall be 2.0. The factored reactions shall be determined by factoring the reactions specified in Article 12.9.4.5.

### 12.9.4.3—Plastic Moment Resistance

The plastic moment resistance of the crown, $M_{pc}$, and the plastic moment resistance of the haunch, $M_{ph}$, shall not be less than the proportioned sum of adjusted dead and live load moments. The values of $M_{pc}$ and $M_{ph}$ shall be determined as follows:

$$M_{pc} \geq C_H P_c \left( M_{d\ell u} + M_{\ell\ell u} \right) \qquad (12.9.4.3\text{-}1)$$

$$M_{ph} \geq C_H \left( 1.0 - P_c \right) \left( M_{d\ell u} + R_h M_{\ell\ell u} \right) \qquad (12.9.4.3\text{-}2)$$

where:

$C_H$ = crown soil cover factor specified in Article 12.9.4.4
$P_c$ = allowable range of the ratio of total moment carried by the crown as specified in Table 12.9.4.3-1
$R_H$ = acceptable values of the haunch moment reduction factor as specified in Table 12.9.4.3-2
$M_{d\ell u}$= factored dead load moment as specified in Article 12.9.4.2 (kip-ft)
$M_{\ell\ell u}$= factored live load moment as specified in Article 12.9.4.2 (kip-ft)

### C12.9.4.3

Some discretion is allowed relative to the total flexural capacity assigned to the crown and haunches of box culverts.

The distribution of moment between the crown and haunch, described in Article C12.9.4.2, is accomplished in the design using the crown moment proportioning factor, $P_c$, which represents the proportion of the total moment that can be carried by the crown of the box culvert and that varies with the relative flexural capacities of the crown and haunch components.

The requirements given herein can be used to investigate products for compliance with these Specifications. Using the actual crown flexural capacity, $M_{pc}$, provided by the metal box structure under consideration and the loading requirements of the application, Eq. 12.9.4.3-1 can be solved for the factor $P_c$, which should fall within the allowable range of Table 12.9.4.3-1. Knowing $P_c$, Eq. 12.9.4.3-2 can be solved for $M_{ph}$, which should not exceed the actual haunch flexural resistance provided by the structure section. If Eq. 12.9.4.3-1 indicates a higher value of $P_c$ than permitted by the allowable ranges in Table 12.9.4.3-1, the actual crown is over designed, which is acceptable. However, in this case, only the maximum value of $P_c$, allowed by Table 12.9.4.3-1, should be used to calculate the required $M_{ph}$ from Eq. 12.9.4.3-2.

**Table 12.9.4.3-1—Crown Moment Proportioning Values, $P_c$, for Spans ≤ 25.0 ft 5.0 in.**

| Span (ft) | Allowable Range of $P_c$ |
|---|---|
| <10.0 | 0.55–0.70 |
| 10.0–15.0 | 0.50–0.70 |
| 15.0–20.0 | 0.45–0.70 |
| 20.0–25.4 | 0.45–0.60 |

**Table 12.9.4.3-2—Crown Moment Positioning Values, $P_c$, for Spans from 25.0 ft 6.0 in. to 36.0 ft 0.0 in.**

| Depth of Fill (ft) | Allowable Range of $P_c$ |
|---|---|
| 1.4–2.5 | 0.55–0.65 |
| 2.5–4.0 | 0.45–0.55 |
| 4.0–5.0 | 0.35–0.55 |

**Table 12.9.4.3-3—Haunch Moment Reduction Values, $R_H$, for Spans ≤ 25.0 ft 5.0 in.**

| | Cover Depth (ft) | | | |
|---|---|---|---|---|
| | 1.4 | 2.0 | 3.0 | 4.0 to 5.0 |
| $R_H$ | 0.66 | 0.74 | 0.87 | 1.00 |

For spans from 25.0 ft 6.0 in. to 36.0 ft 0.0 in., $R_H = 1.0$ for all cover depths.

### 12.9.4.4—Crown Soil Cover Factor, $C_H$

For depths of soil cover greater than or equal to 3.5 ft, the crown soil cover factor, $C_H$, shall be taken as 1.0.

For crown cover depth between 1.4 and 3.5 ft, the crown soil cover factor shall be taken as:

$$C_H = 1.15 - \left(\frac{H - 1.4}{14}\right) \qquad (12.9.4.4\text{-}1)$$

where:

$H$ = depth of cover over crown (ft)

### 12.9.4.5—Footing Reactions

Reactions at the box culvert footing shall be determined as:

$$V = \gamma_s \left(\frac{HS}{2.0} + \frac{S^2}{40.0}\right) + \frac{A_L}{8 + 2\left(H + R\right)} \qquad (12.9.4.5\text{-}1)$$

where:

$V$ = unfactored footing reaction (kip/ft)
$\gamma_s$ = unit weight of backfill (kcf)
$H$ = depth of cover over crown (ft)
$R$ = rise of culvert (ft)

### C12.9.4.4

The results of finite element analyses and field monitoring studies to evaluate the effects of load-induced deformations and in-plane deformed geometries indicate that the design moments should be increased where the cover is less than 3.5 ft.

Eq. 12.9.4.4-1 is discussed in Boulanger et al. (1989).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$S$ = span (ft)
$A_L$ = total axle load (kip)

### 12.9.4.6—Concrete Relieving Slabs

Relieving slabs may be used to reduce flexural moments in box culverts. Relieving slabs shall not be in contact with the crown as shown in Figure 12.9.4.6-1.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the culvert span and sufficient to project 1.0 ft beyond the haunch on each side of the culvert. The relieving slab shall extend across the width subject to vehicular loading.

The depth of reinforced concrete relieving slabs shall be determined as:

$$t = t_b R_{AL} R_c R_f \quad (12.9.4.6\text{-}1)$$

where:

$t$ = minimum depth of slab (in.)
$t_b$ = basic slab depth as specified in Table 12.9.4.6-1 (in.)
$R_{AL}$ = axle load correction factor specified in Table 12.9.4.6-2
$R_c$ = concrete strength correction factor specified in Table 12.9.4.6-3
$R_f$ = factor taken as 1.2 for box structures having spans less than 26.0 ft

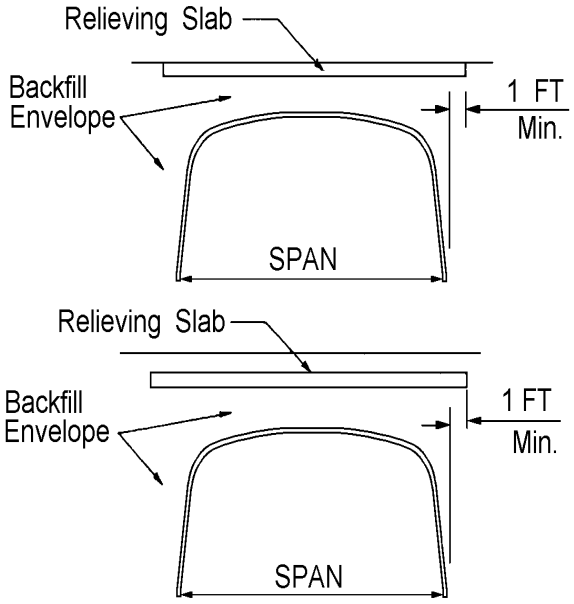

**Figure 12.9.4.6-1—Metal Box Culverts with Concrete Relieving Slab**

### C12.9.4.6

The box culvert design procedure described herein does not directly incorporate consideration of concrete relieving slabs on the influence of concrete pavement. Therefore, the procedures described in Duncan et al. (1985) should be used instead. At this time, the beneficial effect of a relieving slab can only be determined by refined soil–structure interaction analyses. The provisions given herein are applicable only for box structures having spans under 26.0 ft. The purpose of avoiding contact between the relieving slab and the culvert is to avoid concentration of the load applied through the slab to the crown of the culvert. As little as 1.0- to 3.0-in. clearance is thought to be sufficient to distribute the load.

Where an Owner requires design for an axle other than the standard 32.0-kip axle, the factor $R_{AL}$ may be used to adjust the depth of a concrete relieving slab as specified in Eq. 12.9.4.6-1.

| 5.0 | 1.01 |
| 5.5 | 0.97 |
| 6.0 | 0.94 |

### 12.9.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26, "Metal Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.10—REINFORCED CONCRETE PIPE

### 12.10.1—General

The provisions herein shall apply to the structural design of buried precast reinforced concrete pipes of circular, elliptical, and arch shapes.

**C12.10.1**

These structures become part of a composite system comprised of the reinforced concrete buried section and the soil envelope.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The structural design of the types of pipes indicated above may proceed by either of two methods:

- The direct design method at the strength limit state as specified in Article 12.10.4.2, or
- The indirect design method at the service limit state as specified in Article 12.10.4.3.

Standard dimensions for these units are shown in AASHTO M 170 and M 170M (ASTM C76 and C76M), M 206M/M 206 (ASTM C506M and C506), M 207M/M 207 (ASTM C507M and C507), M 242M/M 242 (ASTM C655M and C655), and ASTM C1765.

NCHRP 20-07 Task 316 established that while direct design for small diameter pipes could lead to more steel reinforcement than when using indirect design, which results from simplifying conservative assumptions during direct design, either design procedure can be employed.

## 12.10.2 Loading

### 12.10.2.1 Standard Installations

The contract documents shall specify that the foundation bedding and backfill comply with the provisions of Article 27.5.2 of the *AASHTO LRFD Bridge Construction Specifications*.

Minimum compaction requirements and bedding thickness for standard embankment installations and standard trench installations shall be as specified in Tables 12.10.2.1-1 and 12.10.2.1-2, respectively.

**C12.10.2.1**

The four standard installations replace the historic bedding classes. A comprehensive soil–structure interaction analysis and design program (SPIDA) was developed and used to perform soil–structure interaction analyses for the various soil and installation parameters encompassed in the provisions. The SPIDA studies used to develop the standard installations were conducted for positive projection embankment conditions to provide conservative results for other embankment and trench conditions. These studies also conservatively assume a hard foundation and bedding existing beneath the invert of the pipe, plus void and/or poorly compacted material in the haunch areas, 15 degrees to 40 degrees each side of the invert, resulting in a load concentration such that calculated moments, thrusts, and shears are increased.

**Table 12.10.2.1-1—Standard Embankment Installation Soils and Minimum Compaction Requirements**

| Installation Type | Bedding Thickness | Haunch and Outer Bedding | Lower Side |
|---|---|---|---|
| Type 1 | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 95% Category I | 90% Category I, 95% Category II, or 100% Category III |
| Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 90% Category I or 95% Category II | 85% Category I, 90% Category II, or 95% Category III |
| Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 85% Category I, 90% Category II, or 95% Category III | 85% Category I, 90% Category II, or 95% Category III |
| Type 4 | For soil foundation, no bedding required. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | No compaction required, except if Category III, use 85% Category III | No compaction required, except if Category III, use 85% Category III |

The following interpretations apply to Table 12.10.2.1-1:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Compaction and soil symbols (that is, 95 percent Category I) shall be taken to refer to a soil material category with a minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.
- Soil in the outer bedding, haunch, and lower side zones, except within $B_c/3$ from the pipe springline, shall be compacted to at least the same compaction as the majority of soil in the overfill zone.
- The minimum width of a subtrench shall be $1.33B_c$, or wider if required for adequate space to attain the specified compaction in the haunch and bedding zones.
- For subtrenches with walls of natural soil, any portion of the lower side zone in the subtrench wall shall be at least as firm as an equivalent soil placed to the compaction requirements specified for the lower side zone and as firm as the majority of soil in the overfill zone. Otherwise, it shall be removed and replaced with soil compacted to the specified level.
- A subtrench is defined as a trench in the natural material under an embankment used to retain bedding material with its top below finished grade by more than ten percent of the depth of soil cover on the top of the culvert or pipe. For roadways, the top of a subtrench is at an elevation lower than 1.0 ft below the bottom of the pavement base material.

**Table 12.10.2.1-2—Standard Trench Installation Soils and Minimum Compaction Requirements**

| Installation Type | Bedding Thickness | Haunch and Outer Bedding | Lower Side |
|---|---|---|---|
| Type 1 | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 95% Category I | 90% Category I, 95% Category II, or 100% Category III, or natural soils of equal firmness |
| Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 90% Category I or 95% Category II | 85% Category I, 90% Category II, 95% Category III, or natural soils of equal firmness |
| Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe | For soil foundation, use $D_o$/24.0 in. minimum, not less than 3.0 in. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | 85% Category I, 90% Category II or 95% Category III | 85% Category I, 90% Category II, 95% Category III, or natural soils of equal firmness |
| Type 4 | For soil foundation, no bedding required. For rock foundation, use $D_o$/12.0 in. minimum, not less than 6.0 in. | No compaction required, except if Category III, use 85% Category III | No compaction required except if Category III, use 85% Category III, or natural soil of equal firmness |

The following interpretations apply to Table 12.10.2.1-2:

- Compaction and soil symbols (that is, 95 percent Category I) shall be taken to refer to a soil material category with a minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- The trench top elevation shall be no lower than $0.1H$ below finish grade; for roadways, its top shall be no lower than an elevation of 1.0 ft below the bottom of the pavement base material.
- Soil in bedding and haunch zones shall be compacted to at least the same compaction as specified for the majority of soil in the backfill zone.

If required for adequate space to attain the specified compaction in the haunch and bedding zones the trench width shall be wider than that shown in Figures 27.5.2.2-1 and 27.5.2.2-2 of the *AASHTO LRFD Bridge Construction Specifications*.

- For trench walls that are within 10 degrees of vertical, the compaction or firmness of the soil in the trench walls and lower side zone need not be considered.
- For trench walls with greater than 10 degrees slopes that consist of embankment, the lower side shall be compacted to at least the same compaction as specified for the soil in the backfill zone.

The unfactored earth load, $W_E$, shall be determined as:

$$W_E = F_e w B_c H \quad (12.10.2.1\text{-}1)$$

where:

$W_E$ = unfactored earth load (kip/ft)
$F_e$ = soil–structure interaction factor for the specified installation as defined herein
$B_c$ = out-to-out horizontal dimension of pipe (ft)
$H$ = height of fill above top of pipe (ft)
$w$ = unit weight of soil (pcf)

The unit weight of soil used to calculate earth load shall be the estimated unit weight for the soils specified for the pipe soil installation but shall not be taken to be less than 110 lb/ft$^3$.

Standard installations for both embankments and trenches shall be designed for positive projection, embankment loading conditions where $F_e$ shall be taken as the vertical arching factor, *VAF*, specified in Table 12.10.2.1-3 for each type of standard installation.

For standard installations, the earth pressure distribution shall be the Heger pressure distribution shown in Figure 12.10.2.1-1 and Table 12.10.2.1-3 for each type of standard installation.

The product $wB_cH$ is sometimes referred to as the prism load, *PL*, the weight of the column of earth over the outside diameter of the pipe.

The earth load for designing pipe using a standard installation is obtained by multiplying the weight of the column of earth above the outside diameter of the pipe by the soil–structure interaction factor, $F_e$, for the design installation type. $F_e$ accounts for the transfer of some of the overburden soil above the regions at the sides of the pipe because the pipe is more rigid than the soil at the side of the pipe for pipe in embankment and wide trench installations. Because of the difficulty of controlling maximum trench width in the field with the widespread use of trench boxes or sloped walls for construction safety, the potential reduction in earth load for pipe in trenches of moderate to narrow width is not taken into account in the determination of earth load and earth pressure distribution on the pipe. Both trench and embankment installations are to be designed for embankment (positive projecting) loads and pressure distribution in direct design or bedding factors in indirect design.

The earth pressure distribution and lateral earth force for a unit vertical load is the Heger pressure distribution and horizontal arching factor, *HAF*. The normalized pressure distribution and *HAF* values were obtained for each standard installation type from the results of soil–structure interaction analyses using SPIDA, together with the minimum soil properties for the soil types and compaction levels specified for the installations.

When nonstandard installations are used, the earth load and pressure distribution should be determined by an appropriate soil–structure interaction analysis.

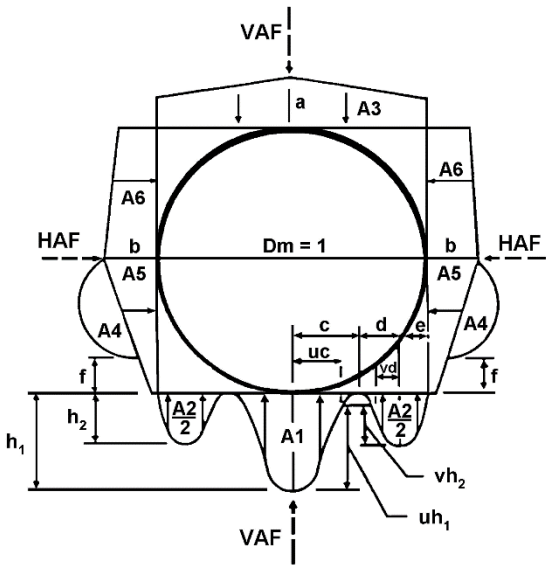

**Figure 12.10.2.1-1—Heger Pressure Distribution and Arching Factors**

**Table 12.10.2.1-3—Coefficients for Use with Figure 12.10.2.1-1**

| | Installation Type | | | |
|---|---|---|---|---|
| | 1 | 2 | 3 | 4 |
| *VAF* | 1.35 | 1.40 | 1.40 | 1.45 |
| *HAF* | 0.45 | 0.40 | 0.37 | 0.30 |
| *A*1 | 0.62 | 0.85 | 1.05 | 1.45 |
| *A*2 | 0.73 | 0.55 | 0.35 | 0.00 |
| *A*3 | 1.35 | 1.40 | 1.40 | 1.45 |
| *A*4 | 0.19 | 0.15 | 0.10 | 0.00 |
| *A*5 | 0.08 | 0.08 | 0.10 | 0.11 |
| *A*6 | 0.18 | 0.17 | 0.17 | 0.19 |
| *a* | 1.40 | 1.45 | 1.45 | 1.45 |
| *b* | 0.40 | 0.40 | 0.36 | 0.30 |
| *c* | 0.18 | 0.19 | 0.20 | 0.25 |
| *e* | 0.08 | 0.10 | 0.12 | 0.00 |
| *f* | 0.05 | 0.05 | 0.05 | — |
| *u* | 0.80 | 0.82 | 0.85 | 0.90 |
| *v* | 0.80 | 0.70 | 0.60 | — |

The following shall apply to Table 12.10.2.1-3:

- *VAF* and *HAF* are vertical and horizontal arching factors. These coefficients represent nondimensional total vertical and earth loads on the pipe, respectively. The actual total vertical and horizontal loads are (*VAF*) × (*PL*) and (*HAF*) × (*PL*), respectively, where *PL* is the prism load.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- Coefficients $A1$ through $A6$ represent the integration of nondimensional vertical and horizontal components of soil pressure under the indicated portions of the component pressure diagrams, i.e., the area under the component pressure diagrams.
- The pressures are assumed to vary either parabolically or linearly, as shown in Figure 12.10.2.1-1, with the nondimensional magnitudes at governing points represented by $h_1$, $h_2$, $uh_1$, $vh_2$, $a$, and $b$.
- Nondimensional horizontal and vertical dimensions of component pressure regions are defined by $c$, $d$, $e$, $uc$, $vd$, and $f$ coefficients,

where:

$$d = \left(0.5 - c - e\right) \tag{12.10.2.1-2}$$

$$h_1 = \left(1.5A1\right)/\left(c\right)\left(1+u\right) \tag{12.10.2.1-3}$$

$$h_2 = \left(1.5A2\right)/\left[\left(d\right)\left(1+v\right)+\left(2e\right)\right] \tag{12.10.2.1-4}$$

**12.10.2.2 Pipe Fluid Weight**

The unfactored weight of fluid, $W_F$, in the pipe shall be considered in design based on a fluid weight of 62.4 lb/ft$^3$, unless otherwise specified. For standard installations, the fluid weight shall be supported by vertical earth pressure that is assumed to have the same distribution over the lower part of the pipe as given in Figure 12.10.2.1-1 for earth load.

**12.10.2.3—Live Loads**

Live loads shall be as specified in Article 3.6 and shall be distributed through the earth cover as specified in Article 3.6.1.2.6. For standard installations, the live load on the pipe shall be assumed to have a uniform vertical distribution across the top of the pipe and the same distribution across the bottom of the pipe as given in Figure 12.10.2.1-1.

**12.10.3—Service Limit State**

The width of cracks in the wall shall be investigated at the service limit state for moment and thrust. Generally, the crack width should not exceed 0.01 in.

## 12.10.4—Safety Against Structural Failure

### 12.10.4.1—General

The resistance of buried reinforced concrete pipe structures against structural failure shall be determined at the strength limit state for:

- Flexure,
- Thrust,
- Shear, and
- Radial tension.

The dimensions of pipe sections shall be determined using either the analytically-based direct design method or the empirically-based indirect design method.

When quadrant mats, stirrups, and/or elliptical cages are specified in the contract documents, the orientation of the pipe installation shall be specified, and the design shall account for the possibility of an angular misorientation of 10 degrees during the pipe installation.

### C12.10.4.1

The direct design method uses a pressure distribution on the pipe from applied loads and bedding reactions based on a soil–structure interaction analysis or an elastic approximation. The indirect design method uses empirically-determined bedding factors that relate the total factored earth load to the concentrated loads and reactions applied in three-edge bearing tests.

### 12.10.4.2—Direct Design Method

#### *12.10.4.2.1—Loads and Pressure Distribution*

The total vertical load acting on the pipe shall be determined as specified in Article 12.10.2.1.

The pressure distribution on the pipe from applied loads and bedding reaction shall be determined from either a soil–structure analysis or from a rational approximation, either of which shall permit the development of a pressure diagram, shown schematically in Figure 12.10.4.2.1-1, and the analysis of the pipe.

#### *C12.10.4.2.1*

The direct design method was accepted in 1993 by ASCE and is published in ASCE 93-15, *Standard Practice for Direct Design of Buried Precast Concrete Pipe Using Standard Installations* (SIDD). The design method was developed along with the research performed on the standard installations. However, the design equations are applied after the required flexural moments, thrusts, and shear forces at all critical sections have been determined using any one of the acceptable pressure distributions. Therefore, the use of the design equations herein is not limited to the standard installations or any one assumed pressure distribution.

Direct design requires:

- The determination of earth loads and live load pressure distributions on the structure for the bedding and installation conditions selected by the Engineer;
- Analysis to determine thrust, moments, and shears; and
- Design to determine circumferential reinforcement.

The procedures for analysis and design are similar to those used for other reinforced concrete structures.

*12.10.4.2.2—Analysis for Force Effects with the Pipe Ring*

Force effects in the pipe shall be determined by an elastic analysis of the pipe ring under the assumed pressure distribution or a soil–structure analysis.

If thin ring theory is employed, the expected moments at crown and invert can be adjusted to account for ring thickness by:

$$M_{thick} = M_{thin}\left(1 - 0.373\ \frac{t}{R}\right) \qquad (12.10.4.2.2\text{-}1)$$

where:

$M_{thick}$ = adjusted moment
$M_{thin}$ = moment calculated using thin ring theory
$t$ = thickness of the concrete pipe
$R$ = average radius of the concrete pipe

*C12.10.4.2.2*

NCHRP 20-07 Task 316 established that the discrepancies in quantities of flexural reinforcement resulting from direct and indirect design are partly due to the use of thin ring theory. Adjustment to account for thick ring theory resolves those discrepancies in part, though much of the conservatism of direct design remains (for example, the estimation of expected moment and consideration of ultimate limit state based on first plastic moment).

*12.10.4.2.3—Process and Material Factors*

Process and material factors, $F_{rp}$ for radial tension and $F_{vp}$ for shear strength, for design of plant-made reinforced concrete pipe should be taken as 1.0. Higher values of these factors may be used if substantiated by sufficient testing in accordance with AASHTO M 242M/M 242 (ASTM C655M and C655).

*12.10.4.2.4—Flexural Resistance at the Strength Limit State*

*12.10.4.2.4a—Circumferential Reinforcement*

Reinforcement for flexural resistance provided in a length, $b$, usually taken as 12.0 in., shall satisfy:

$$A_s \geq \frac{g\phi d - N_u - \sqrt{g\left[g\left(\phi d\right)^2 - N_u\left(2\phi d - h\right) - 2M_u\right]}}{f_y} \qquad (12.10.4.2.4a\text{-}1)$$

in which:

$$g = 0.85bf'_c \qquad (12.10.4.2.4a\text{-}2)$$

where:

$A_s$ = area of reinforcement per length of pipe, $b$ (in.$^2$/ft)
$f_y$ = specified yield strength of reinforcing less than or equal to 80 ksi
$d$ = distance from compression face to centroid of tension reinforcement (in.)
$h$ = wall thickness of pipe (in.)
$M_u$ = moment due to factored loads (kip-in./ft)

*C12.10.4.2.4a*

NCHRP 20-07 Task 316 established that more sophisticated procedures can be employed for estimating the flexural and shear resistance at the strength limit state, such as Modified Compression Field Theory, to enforce compatibility between steel and concrete components and account for multiple layers of steel reinforcement and nonlinear concrete and steel behavior.

The required area of steel, $A_s$, as determined by Eq. 12.10.4.2.4a-1, should be distributed over a unit length of the pipe, $b$, which is typically taken as 12.0 in.

The factored actions should also be consistent with the selected unit width.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$N_u$ = thrust due to factored load, taken to be positive for compression (kip/ft)
$\phi$ = resistance factor for flexure specified in Article 12.5.5

*12.10.4.2.4b—Minimum Reinforcement*

The reinforcement, $A_s$, per ft of pipe shall not be less than:

- For inside face of pipe with two layers of reinforcement:

$$A_s \geq \frac{(S_i + h)^2}{1{,}000 f_y} \geq 0.07 \qquad (12.10.4.2.4b\text{-}1)$$

- For outside face of pipe with two layers of reinforcement:

$$A_s \geq 0.60\frac{(S_i + h)^2}{1{,}000 f_y} \geq 0.07 \qquad (12.10.4.2.4b\text{-}2)$$

- For elliptical reinforcement in circular pipe and for 33.0-in. diameter and smaller pipe with a single cage of reinforcement in the middle third of the pipe wall:

$$A_s \geq 2\frac{(S_i + h)^2}{1{,}000 f_y} \geq 0.07 \qquad (12.10.4.2.4b\text{-}3)$$

where:

$S_i$ = internal diameter or horizontal span of the pipe (in.)
$h$ = wall thickness of pipe (in.)
$f_y$ = yield strength of reinforcement less than or equal to 80 ksi

*12.10.4.2.4c—Maximum Flexural Reinforcement without Stirrups*

The flexural reinforcement per ft of pipe without stirrups shall satisfy:

- For inside steel in radial tension:

$$A_{smax} \leq \frac{0.506 r_s F_{rp} \sqrt{f'_c}(R_\phi) F_{rt}}{f_y} \qquad (12.10.4.2.4c\text{-}1)$$

where:

$A_{smax}$ = minimum flexural reinforcement area without stirrups (in.$^2$/ft)
$r_s$ = radius of the inside reinforcement (in.)
$f'_c$ = compressive strength of concrete (ksi)
$f_y$ = specified yield strength of reinforcement less than or equal to 80 ksi

*C12.10.4.2.4c*

Research has shown that reinforcing steel with yield strengths up to 80 ksi can be used in the flexural design of concrete. Eqs. 12.10.4.2.4c-1 and 12.10.4.2.4c-2 utilize the reinforcing yield stress times the area of reinforcement to establish a tension force applied to the concrete. Higher reinforcing yield strengths will result in higher tension forces for an equivalent area of steel. Thus, the allowable maximum steel area is less when utilizing high strength reinforcement. Therefore, the same reinforcing yield strength value used in determining the flexural reinforcement area in Eq. 12.10.4.2.4a-1 should be used in Eqs. 12.10.4.2.4c-1 and 12.10.4.2.4c-2.

All rights reserved. Duplication is a violation of applicable law.

$R_\phi$ = ($\phi_r/\phi_f$); ratio of resistance factors for radial tension and moment specified in Article 12.5.5
$F_{rp}$ = 1.0 unless a higher value substantiated by test data and approved by the Engineer

in which:

- For 12.0 in. ≤ $S_i$ ≤ 72.0 in.

  $F_{rt} = 1 + 0.00833\ (72 - S_i)$

- For 72.0 in. < $S_i$ ≤ 144.0 in.:

$$F_{rt} = \frac{(144 - S_i)^2}{26,000} + 0.80$$

- For $S_i$ > 144.0 in.:

  $F_{rt} = 0.80$

- For reinforcing steel in compression:

$$A_{smax} \le \frac{\left[\left(\frac{55g'\phi d}{87 + f_y}\right) - 0.75N_u\right]}{f_y} \qquad (12.10.4.2.4c\text{-}2)$$

in which:

$$g' = b\,f_c'\,[0.85 - 0.05\,(f_c' - 4.0)] \qquad (12.10.4.2.4c\text{-}3)$$

$$0.85\,b\,f_c' \ge g' \ge 0.65\,b\,f_c' \qquad (12.10.4.2.4c\text{-}4)$$

where:

$b$ = width of section taken as 12.0 in.
$\phi$ = resistance factor for flexure as specified in Article 5.5.4.2
$f_y$ = specified yield strength of reinforcing less than or equal to 80 ksi

*12.10.4.2.4d—Reinforcement for Crack Width Control*

The crack width factor, $F_{cr}$, may be determined as:

- If $N_s$ is compressive, it is taken as positive and:

$$F_{cr} = \frac{B_1}{30\phi dA_s}\left[\frac{M_s + N_s\left(d - \frac{h}{2}\right)}{ij} - 0.0316C_1bh^2\sqrt{f_c'}\right] \qquad (12.10.4.2.4d\text{-}1)$$

- If $N_s$ is tensile, it is taken as negative and:

$$F_{cr} = \frac{B_1}{30dA_s\phi}\left(1.1M_s - 0.6N_sd - 0.0316C_1bh^2\sqrt{f_c'}\right) \qquad (12.10.4.2.4d\text{-}2)$$

*C12.10.4.2.4d*

The crack control coefficients, $B_1$ and $C_1$, are dependent on the type of reinforcement.

Crack control is assumed to be 1.0 in. from the closest tension reinforcement, even if the cover over the reinforcement is greater than or less than 1.0 in. The crack control factor, $F_{cr}$, in Eq. 12.10.4.2.4d-1 indicates the probability that a crack of a specified maximum width will occur.

If the ratio of $e/d$ is less than 1.15, crack control will not govern.

in which:

$$j = 0.74 + 0.1\frac{e}{d} \le 0.9 \qquad (12.10.4.2.4d\text{-}3)$$

$$i = \frac{1}{\left(1 - \frac{jd}{e}\right)} \qquad (12.10.4.2.4d\text{-}4)$$

$$e = \frac{M_s}{N_s} + d - \frac{h}{2} \qquad (12.10.4.2.4d\text{-}5)$$

$$B_1 = \left(\frac{t_b S_\ell}{2n}\right)^{\frac{1}{3}} \qquad (12.10.4.2.4d\text{-}6)$$

where:

$M_s$ = flexural moment at service limit state (kip-in./ft)
$N_s$ = axial thrust at service limit state (kip/ft)
$d$ = distance from compression face to centroid of tension reinforcement (in.)
$h$ = wall thickness (in.)
$f'_c$ = specified compressive strength of concrete (ksi)
$C_1$ = crack control coefficient for various types of reinforcement as specified in Table 12.10.4.2.4d-1
$A_s$ = area of steel (in.$^2$/ft)
$i$ = coefficient for effect of axial force at service limit state, $f_s$
$j$ = coefficient for moment arm at service limit state, $f_s$
$b$ = width of section taken as 12.0 in.
$t_b$ = clear cover over reinforcement (in.)
$S_\ell$ = spacing of circumferential reinforcement (in.)
$n$ = 1.0 when tension reinforcement is a single layer
$n$ = 2.0 when tension reinforcement is made of multiple layers
$\phi$ = resistance factor for flexure as specified in Article 12.5.5

**Table 12.10.4.2.4d-1—Crack Control Coefficients**

| Type | Reinforcement | $C_1$ |
|---|---|---|
| 1 | Smooth wire or plain bars | 1.0 |
| 2 | Welded smooth wire fabric with 8.0-in. maximum spacing of longitudinals, welded deformed wire fabric, or deformed wire | 1.5 |
| 3 | Deformed bars or any reinforcement with stirrups anchored thereto | 1.9 |

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

For Type 2 reinforcement in Table 12.10.4.2.4d-1 having $t_b^2 S_l/n > 3.0$, the crack width factor, $F_{cr}$, shall also be investigated using coefficients $B_1$ and $C_1$ specified for Type 3 reinforcement, and the larger value for $F_{cr}$ shall be used.

Higher values for $C_1$ may be used if substantiated by test data and approved by the Engineer.

Where $F_{cr}$ = 1.0, the specified reinforcement is expected to produce an average maximum crack width of 0.01 in. For $F_{cr} < 1.0$, the probability of a 0.01-in. crack is reduced, and for $F_{cr} > 1.0$, it is increased.

*12.10.4.2.4e—Minimum Concrete Cover*

The provisions of Article 5.10.1 shall apply to minimum concrete cover, except as follows:

- If the wall thickness is less than 2.5 in., the cover shall not be less than 0.75 in., and
- If the wall thickness is not less than 2.5 in., the cover shall not be less than 1.0 in.

*12.10.4.2.5—Shear Resistance without Stirrups*

*C12.10.4.2.5*

The section shall be investigated for shear at a critical section taken where $M_{nu}/(V_u d) = 3.0$. The factored shear resistance without radial stirrups, $V_r$, shall be taken as:

$$V_r = \phi V_n \qquad (12.10.4.2.5\text{-}1)$$

in which:

$$V_n = 0.0316 b d F_{vp} \sqrt{f'_c}(1.1 + 63\rho)\left(\frac{F_d F_n}{F_c}\right) \qquad (12.10.4.2.5\text{-}2)$$

$$\rho = \frac{A_s}{bd} \le 0.02 \qquad (12.10.4.2.5\text{-}3)$$

- For pipes with two cages or a single elliptical cage:

$$F_d = 0.8 + \frac{1.6}{d} \le 1.3 \qquad (12.10.4.2.5\text{-}4)$$

For the purpose of this Article, a cage is considered to be a layer of reinforcement.

- For pipes not exceeding 36.0-in. diameter with a single circular cage:

$$F_d = 0.8 + \frac{1.6}{d} \le 1.4 \qquad (12.10.4.2.5\text{-}5)$$

If $N_u$ is compressive, it is taken as positive and:

$$F_n = 1 + \frac{N_u}{24h} \qquad (12.10.4.2.5\text{-}6)$$

If $N_u$ is tensile, it is taken as negative and:

$$F_n = 1 + \frac{N_u}{6h} \qquad (12.10.4.2.5\text{-}7)$$

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$F_c = 1 \pm \frac{d}{2r} \qquad (12.10.4.2.5\text{-}8)$$

$$M_{nu} = M_u - N_u \left[ \frac{(4h - d)}{8} \right] \qquad (12.10.4.2.5\text{-}9)$$

The algebraic sign in Eq. 12.10.4.2.5-8 shall be taken as positive where tension is on the inside of the pipe and negative where tension is on the outside of the pipe.

where:

$f'_{cmax}$ = 7.0 ksi
$b$ = width of design section taken as 12.0 in.
$d$ = distance from compression face to centroid of tension reinforcement (in.)
$h$ = wall thickness (in.)
$\phi$ = resistance factor for shear as specified in Article 5.5.4.2
$r$ = radius to centerline of concrete pipe wall (in.)
$N_u$ = thrust due to factored loads (kip/ft)
$V_u$ = shear due to factored loads (kip/ft)
$F_{vp}$ = process and material factor specified in Article 12.10.4.2.3

If the factored shear resistance, as determined herein, is not adequate, radial stirrups shall be provided in accordance with Article 12.10.4.2.6.

*12.10.4.2.6—Shear Resistance with Radial Stirrups*

Radial tension and shear stirrup reinforcement shall not be less than:

- For radial tension:

$$A_{vr} = \frac{1.1 s_v (M_u - 0.45 N_u \phi_r d)}{f_y r_s \phi_r d} \qquad (12.10.4.2.6\text{-}1)$$

$$s_v \le 0.75 \phi_r d \qquad (12.10.4.2.6\text{-}2)$$

- For shear:

$$A_{vs} = \frac{1.1 s_v}{f_y \phi_v d} \left( V_u F_c - V_c \right) + A_{vr} \qquad (12.10.4.2.6\text{-}3)$$

$$s_v \le 0.75 \phi_v d \qquad (12.10.4.2.6\text{-}4)$$

in which:

$$V_c = \frac{4 V_r}{\frac{M_{nu}}{V_u d} + 1} \le 0.0633 \phi_v b d \sqrt{f'_c} \qquad (12.10.4.2.6\text{-}5)$$

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

where:

$M_u$ = flexural moment due to factored loads (kip-in./ft)
$M_{nu}$ = factored moment acting on cross-section width, $b$, as modified for effects of compressive or tensile thrust (kip-in./ft)
$N_u$ = thrust due to factored loads (kip/ft)
$V_u$ = shear due to factored loads (kip/ft)
$V_c$ = shear resistance of concrete section (kip/ft)
$d$ = distance from compression face to centroid of tension reinforcement (in.)
$f_y$ = specified yield strength for reinforcement; the value of $f_y$ shall be taken as the lesser of the yield strength of the stirrup or its developed anchorage capacity (ksi)
$r_s$ = radius of inside reinforcement (in.)
$s_v$ = spacing of stirrups (in.)
$V_r$ = factored shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft)
$A_{vr}$ = stirrup reinforcement area to resist radial tension forces on cross-section width, $b$, in each line of stirrups at circumferential spacing, $s_v$ (in.$^2$/ft)
$A_{vs}$ = required area of stirrups for shear reinforcement (in.$^2$/ft)
$f'_c$ = compressive strength of concrete (ksi)
$\phi_v$ = resistance factor for shear as specified in Article 12.5.5
$\phi_r$ = resistance factor for radial tension as specified in Article 12.5.5
$F_c$ = curvature factor as determined by Eq. 12.10.4.2.5-8

*12.10.4.2.7—Stirrup Reinforcement Anchorage*

*12.10.4.2.7a—Radial Tension Stirrup Anchorage*

When stirrups are used to resist radial tension, they shall be anchored around each circumferential of the inside cage to develop the resistance of the stirrup, and they shall also be anchored around the outside cage or embedded sufficiently in the compression side to develop the required resistance of the stirrup.

*12.10.4.2.7b—Shear Stirrup Anchorage*

Except as specified herein, when stirrups are not required for radial tension but required for shear, their longitudinal spacing shall be such that they are anchored around each tension circumferential or every other tension circumferential. The spacing of such stirrups shall not exceed 6.0 in.

*C12.10.4.2.7a*

Stirrup reinforcement anchorage development research by pipe manufacturers has demonstrated that the free ends of loop-type stirrups need only be anchored in the compression zone of the concrete cross-section to develop the full tensile strength of the stirrup wire. Stirrup loop lengths equivalent to 70 percent of the wall thickness may be considered to provide adequate anchorage.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*12.10.4.2.7c—Stirrup Embedment*

Stirrups intended to resist forces in the invert and crown regions shall be anchored sufficiently in the opposite side of the pipe wall to develop the required resistance of the stirrup.

**12.10.4.3—Indirect Design Method**

*12.10.4.3.1—Bearing Resistance*

*C12.10.4.3.1*

The indirect design method has been the most commonly utilized method of design for buried reinforced concrete pipe. It is based on correlating the stress on the pipe in the field to the stress on the pipe when tested in the three-edge bearing apparatus.

The required D-load at which the pipe develops its ultimate strength in a three-edge bearing test is the design D-load at service, as calculated in Eq. 12.10.4.3.1-1, multiplied by a strength factor specified in the manufacturing standard. For conventionally reinforced concrete pipe produced to AASHTO M 170M and M 170 (ASTM C76M and C76), M 242M/M 242 (ASTM 655M and C655), M 206M/M 206 (ASTM C506M and C506) or M 207M/M 207 (ASTM C507M and C507) the service load criteria in the three-edge bearing test is a 0.01-in. crack. For fiber reinforced concrete pipe produced to ASTM C1765, a 0.01-in. crack is not reached at the design service load. Thus, the pipes are tested to ultimate strength in the three-edge bearing test.

Earth and live loads on the pipe shall be determined in accordance with Article 12.10.2 and compared to three-edge bearing strength D-load for the pipe. The service limit state shall apply using the criterion of acceptable crack width specified herein.

The D-load for a particular class and size of pipe shall be determined in accordance with AASHTO M 170M and M 170 (ASTM C76M and C76), M 206M/M 206 (ASTM C506M and C506), M 207M/M 207 (ASTM C507M and C507), M 242M/M 242 (ASTM C655M and C655), or ASTM C1765.

The three-edge bearing resistance of the reinforced concrete pipe, corresponding to an experimentally tested service load, shall not be less than the design load determined for the pipe as installed, taken as:

$$D = \left(\frac{12}{S_i}\right)\left(\frac{W_E + W_F}{B_{FE}} + \frac{W_L}{B_{FLL}}\right) \qquad (12.10.4.3.1\text{-}1)$$

where:

$B_{FE}$ = earth load bedding factor specified in Article 12.10.4.3.2a or Article 12.10.4.3.2b
$B_{FLL}$ = live load bedding factor specified in Article 12.10.4.3.2c
$S_i$ = internal diameter of pipe (in.)
$W_E$ = total unfactored earth load specified in Article 12.10.2.1 (kip/ft)
$W_F$ = total unfactored fluid load in the pipe as specified in Article 12.10.2.2 (kip/ft)
$W_L$ = total unfactored live load on unit length pipe specified in Article 12.10.2.3 (kip/ft)

For Type 1 installations, $D$ loads, as calculated above, shall be modified by multiplying by an installation factor of 1.10.

*12.10.4.3.2—Bedding Factor*

*C12.10.4.3.2*

The minimum compaction specified in Tables 12.10.2.1-1 and 12.10.2.1-2 shall be required by the contract document.

The bedding factor is the ratio of the moment at service limit state to the moment applied in the three-edge bearing test. The standard supporting strength of buried pipe depends on the type of installation. The bedding factors given herein are based on the minimum levels of compaction indicated.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*12.10.4.3.2a—Earth Load Bedding Factor for Circular Pipe*

*C12.10.4.3.2a*

Earth load bedding factors, $B_{FE}$, for circular pipe are presented in Table 12.10.4.3.2a-1.

For pipe diameters, other than those listed in Table 12.10.4.3.2a-1, embankment condition bedding factors, $B_{FE}$, may be determined by interpolation.

The bedding factors for circular pipe were developed using the flexural moments produced by the Heger pressure distributions from Figure 12.10.2.1-1 for each of the standard embankment installations. The bedding factors for the embankment condition are conservative for each installation. This conservatism is based on assuming voids and poor compaction in the haunch areas and a hard bedding beneath the pipe in determining the moments, thrusts, and shears used to calculate the bedding factors. The modeling of the soil pressure distribution used to determine moments, thrusts, and shears is also conservative by 10–20 percent, compared with the actual SPIDA analysis.

**Table 12.10.4.3.2a-1—Bedding Factors for Circular Pipe**

| Pipe Diameter, in. | Standard Installations | | | |
|---|---|---|---|---|
| | Type 1 | Type 2 | Type 3 | Type 4 |
| 12 | 4.4 | 3.2 | 2.5 | 1.7 |
| 24 | 4.2 | 3.0 | 2.4 | 1.7 |
| 36 | 4.0 | 2.9 | 2.3 | 1.7 |
| 72 | 3.8 | 2.8 | 2.2 | 1.7 |
| 144 | 3.6 | 2.8 | 2.2 | 1.7 |

*12.10.4.3.2b—Earth Load Bedding Factor for Arch and Elliptical Pipe*

The bedding factor for installation of arch and elliptical pipe shall be taken as:

$$B_{FE} = \frac{C_A}{C_N - xq} \qquad (12.10.4.3.2b\text{-}1)$$

where:

$C_A$ = constant corresponding to the shape of the pipe, as specified in Table 12.10.4.3.2b-1
$C_N$ = parameter that is a function of the distribution of the vertical load and vertical reaction, as specified in Table 12.10.4.3.2b-1
$x$ = parameter that is a function of the area of the vertical projection of the pipe over which lateral pressure is effective, as specified in Table 12.10.4.3.2b-1
$q$ = ratio of the total lateral pressure to the total vertical fill load specified herein

Design values for $C_A$, $C_N$, and $x$ are listed in Table 12.10.4.3.2b-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**Table 12.10.4.3.2b-1—Design Values of Parameters in Bedding Factor Equation**

| Pipe Shape | $C_A$ | Installation Type | $C_N$ | Projection Ratio, $p$ | $x$ |
|---|---|---|---|---|---|
| Horizontal Elliptical and Arch | 1.337 | 2 | 0.630 | 0.9 | 0.421 |
| | | | | 0.7 | 0.369 |
| | | 3 | 0.763 | 0.5 | 0.268 |
| | | | | 0.3 | 0.148 |
| Vertical Elliptical | 1.021 | 2 | 0.516 | 0.9 | 0.718 |
| | | | | 0.7 | 0.639 |
| | | 3 | 0.615 | 0.5 | 0.457 |
| | | | | 0.3 | 0.238 |

The value of the parameter $q$ is taken as:

- For arch and horizontal elliptical pipe:

$$q = 0.23\frac{p}{F_e}\left(1 + 0.35p\frac{B_c}{H}\right) \qquad (12.10.4.3.2b\text{-}2)$$

- For vertical elliptical pipe:

$$q = 0.48\frac{p}{F_e}\left(1 + 0.73p\frac{B_c}{H}\right) \qquad (12.10.4.3.2b\text{-}3)$$

where:

$p$ = projection ratio, ratio of the vertical distance between the outside top of the pipe, and the ground of bedding surface to the outside vertical height of the pipe

*12.10.4.3.2c—Live Load Bedding Factors*

The bedding factor, $B_{FLL}$, for live load, $W_L$, for both circular pipe and arch and for elliptical pipe shall be taken as specified in Table 12.10.4.3.2c-1. For pipe diameters not listed in Table 12.10.4.3.2c-1, the bedding factor may be determined by interpolation.

**Table 12.10.4.3.2c-1—Bedding Factors, $B_{FLL}$**

| Pipe diameter, in. | Fill Height, ft | |
|---|---|---|
| | < 2.0 ft | ≥ 2.0 ft |
| 12 | 3.2 | 2.4 |
| 18 | 3.2 | 2.4 |
| 24 | 3.2 | 2.4 |
| 30 and larger | 2.2 | 2.2 |

*C12.10.4.3.2c*

The relatively large bending stiffness in the longitudinal direction of concrete pipe results in the distribution of the live load force along the length of the pipe. This ratio of distribution length to pipe diameter is higher in small diameter pipes designed by the Indirect Design Method. The bedding factor has been adjusted in Table 12.10.4.3.2c-1 to account for this higher distribution length.

### 12.10.4.4—Development of Quadrant Mat Reinforcement

*12.10.4.4.1—Minimum Cage Reinforcement*

In lieu of a detailed analysis, when quadrant mat reinforcement is used, the area of the main cage shall be

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

no less than 25 percent of the area required at the point of maximum moment.

*12.10.4.4.2—Development Length of Welded Wire Fabric*

Unless modified herein, the provisions of Article 5.10.8.2.5 shall apply.

*12.10.4.4.3—Development of Quadrant Mat Reinforcement Consisting of Welded Plain Wire Fabric*

The embedment of the outermost longitudinals on each end of the circumferentials shall not be less than:

- the greater of 12 circumferential bar diameters or three-quarters of the wall thickness of the pipe beyond the point where the quadrant reinforcement is no longer required by the orientation angle, and
- a distance beyond the point of maximum flexural stress by the orientation angle plus the development length, $\ell_d$, where $\ell_d$ is specified in Article 5.10.8.2.5.

The mat shall contain no less than two longitudinals at a distance 1.0 in. greater than that determined by the orientation angle from either side of the point requiring the maximum flexural reinforcement.

The point of embedment of the outermost longitudinals of the mat shall be at least a distance determined by the orientation angle past the point where the continuing reinforcement is no less than double the area required for flexure.

*12.10.4.4.4—Development of Quadrant Mat Reinforcement Consisting of Deformed Bars, Deformed Wire, or Deformed Wire Fabric*

When deformed bars, deformed wire, or deformed wire fabric is used, the circumferential bars in quadrant mat reinforcement shall satisfy the following requirements:

- Circumferentials shall extend past the point where they are no longer required by the orientation angle plus the greater of 12 wire or bar diameters or three-quarters of the wall thickness of the pipe,
- Circumferentials shall extend on either side of the point of maximum flexural stress not less than the orientation angle plus the development length, $\ell_{hd}$, as required by Article 5.10.8.2.5a and modified by the applicable modification factor or factors, and
- Circumferentials shall extend at least a distance determined by the orientation angle past the point where the continuing reinforcement is no less than double the area required for flexure.

### 12.10.5—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 27, "Concrete Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.11—REINFORCED CONCRETE CAST-IN-PLACE AND PRECAST BOX CULVERTS AND REINFORCED CAST-IN-PLACE ARCHES

### 12.11.1—General

The provisions herein shall apply to the structural design of cast-in-place and precast reinforced concrete box culverts and cast-in-place reinforced concrete arches with the arch barrel monolithic with each footing.

Designs shall conform to applicable Articles of these Specifications, except as provided otherwise herein.

**C12.11.1**

These structures become part of a composite system comprised of the box or arch culvert structure and the soil envelope.

Precast reinforced concrete box culverts may be manufactured using conventional structural concrete and forms, or they may be machine made with dry concrete and vibrating form pipe making methods.

Standard dimensions for precast reinforced concrete box culverts are shown in AASHTO M 259 (ASTM C789) and M 273 (ASTM C850).

### 12.11.2—Loads and Live Load Distribution

#### 12.11.2.1—General

Loads and load combinations specified in Table 3.4.1-1 shall apply. Live load shall be considered as specified in Article 3.6.1.3. Distribution of wheel loads and concentrated loads for culverts with less than 2.0 ft of fill shall be taken as specified in Article 4.6.2.10. For traffic traveling parallel to the span, box culverts shall be designed for a single loaded lane with the single lane multiple presence factor applied to the load. Requirements for bottom distribution reinforcement in top slabs of such culverts shall be as specified in Article 9.7.3.2 for mild steel reinforcement and Article 5.12.2.1 for prestressed reinforcement.

Distribution of wheel loads to culverts with 2.0 ft or more of cover shall be as specified in Article 3.6.1.2.6.

The dynamic load allowance for buried structures shall conform to Article 3.6.2.2.

For cast-in-place box culverts, and for precast box culverts with top slabs having span-to-thickness ratios ($s/t$) >18 or segment lengths <4.0 ft, edge beams shall be provided as specified in Article 4.6.2.1.4 as follows:

- At ends of culvert runs where wheel loads travel within 24.0 in. from the end of culvert,
- At expansion joints of cast-in-place culverts where wheel loads travel over or adjacent to the expansion joint.

**C12.11.2.1**

For the design of box culverts, three general load combinations envelope all controlling force effects for the Strength and Service limit states. These are:

- Maximum vertical, Maximum horizontal
- Maximum vertical, Minimum horizontal
- Minimum vertical, Maximum horizontal

Controlling force effects with maximum horizontal loads may occur with live load surcharge (LS) present or absent. Both situations should be investigated.

Research into live load distribution on box culverts (McGrath et al., 2004) has shown that design for a single loaded lane with a multiple presence factor of 1.2 on the live load and using the live load distribution widths in Article 4.6.2.10 will provide adequate design loading for multiple loaded lanes with multiple presence factors of 1.0 or less when the traffic direction is parallel to the span.

The edge beam provisions are only applicable for culverts with less than 2.0 ft of fill. Precast box culverts with span-to-thickness ratios ($s/t$) ≤18 have been shown to have significantly more strength than would be predicted by Article 5.7.3 (Garg et al., 2007) (Abolmaali and Garg, 2008). While the distribution of the load when it is applied to the edge of these structures would not be as large as would be predicted by Article 4.6.2.10, the residual strength in the structure more than compensates for the liberal load distribution.

### 12.11.2.2—Modification of Earth Loads for Soil–Structure Interaction

*12.11.2.2.1—Embankment and Trench Conditions*

In lieu of a more refined analysis, the total unfactored earth load, $W_E$, acting on the culvert may be taken as:

- For embankment installations:

$$W_E = F_e \gamma_s B_c H \qquad (12.11.2.2.1\text{-}1)$$

in which:

$$F_e = 1 + 0.20 \frac{H}{B_c} \qquad (12.11.2.2.1\text{-}2)$$

- For trench installations:

$$W_E = F_t \gamma_s B_c H \qquad (12.11.2.2.1\text{-}3)$$

in which:

$$F_t = \frac{C_d B_d^{\,2}}{H B_c} \le F_e \qquad (12.11.2.2.1\text{-}4)$$

where:

$W_E$ = total unfactored earth load (kip/ft)
$B_c$ = outside width of culvert as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2, as appropriate (ft)
$H$ = depth of backfill as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2 (ft)
$F_e$ = soil–structure interaction factor for embankment installation specified herein
$F_t$ = soil–structure interaction factor for trench installations specified herein
$\gamma_s$ = unit weight of backfill (kcf)
$B_d$ = horizontal width of trench as specified in Figure 12.11.2.2.1-2 (ft)
$C_d$ = a coefficient specified in Figure 12.11.2.2.1-3

$F_e$ shall not exceed 1.15 for installations with compacted fill along the sides of the box section, or 1.40 for installations with uncompacted fill along the sides of the box section.

For wide trench installations where the trench width exceeds the horizontal dimension of the culvert across the trench by more than 1.0 ft, $F_t$ shall not exceed the value specified for an embankment installation.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

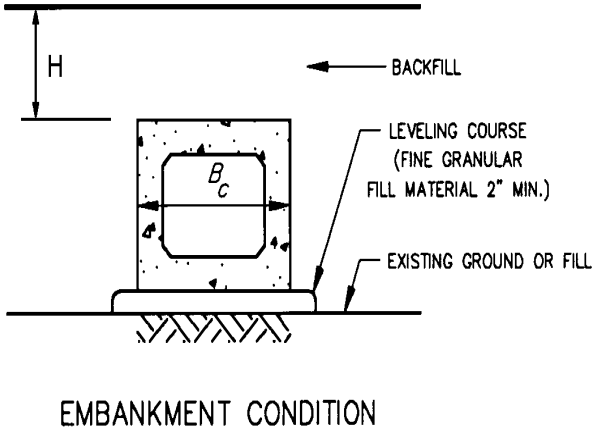

**Figure 12.11.2.2.1-1—Embankment Condition—Precast Concrete Box Sections**

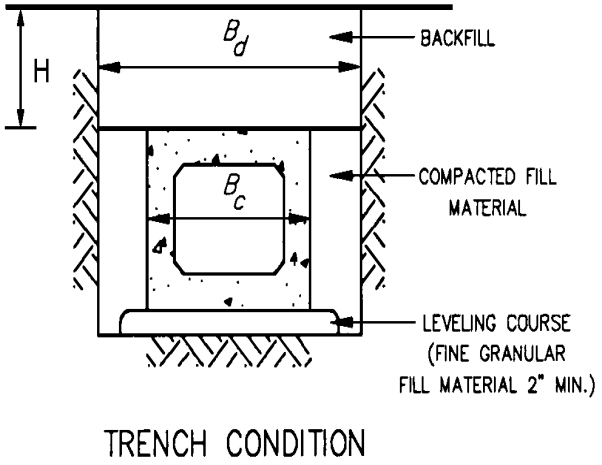

**Figure 12.11.2.2.1-2—Trench Condition—Precast Concrete Box Sections**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

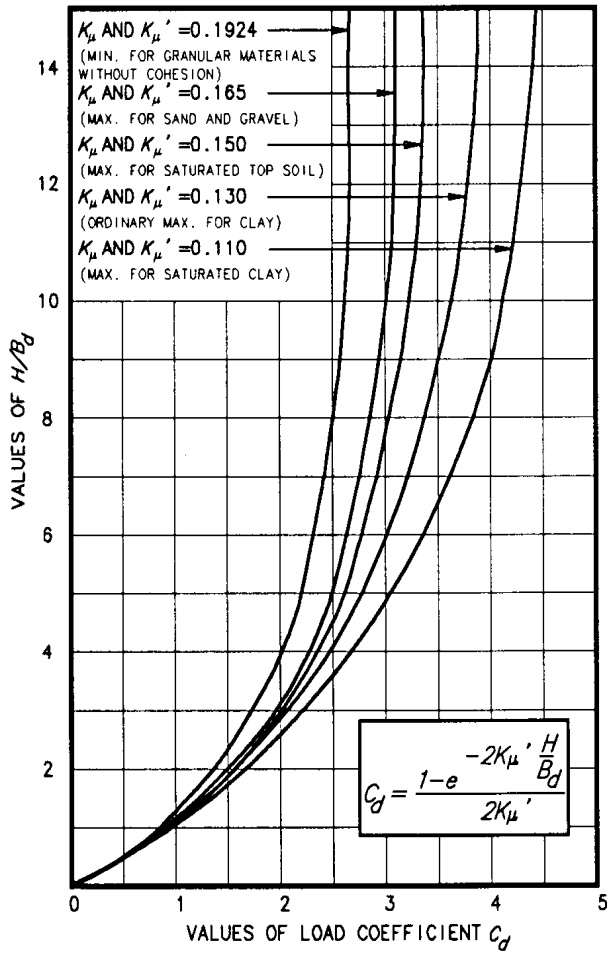

**Figure 12.11.2.2.1-3—Coefficient, $C_d$, for Trench Installations**

*12.11.2.2.2—Other Installations*

Methods of installation other than embankment or trench may be used to reduce the loads on the culvert, including partial positive projection, 0.0 projection, negative projection, induced trench, and jacked installations. The loads for such installations may be determined by accepted methods based on tests, soil–structure interaction analyses, or previous experience.

### 12.11.2.3—Distribution of Concentrated Loads to Bottom Slab of Box Culvert

The width of the top slab strip used for distribution of concentrated wheel loads, specified in Article 12.11.2, shall also be used for the determination of moments, shears, and thrusts in the side walls and the bottom slab.

### C12.11.2.3

Restricting the live load distribution width for the bottom slab to the same width used for the top slab provides designs suitable for multiple loaded lanes, even though analysis is only completed for a single loaded lane (as discussed in Article C12.11.2.1).

While typical designs assume a uniform pressure distribution across the bottom slab, a refined analysis that considers the actual soil stiffness under box sections will result in pressure distributions that reduce bottom slab shear and moment forces (McGrath et al., 2004).

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Such an analysis requires knowledge of in-situ soil properties to select the appropriate stiffness for the supporting soil. A refined analysis taking this into account may be beneficial when analyzing existing culverts.

### 12.11.2.4—Distribution of Concentrated Loads in Skewed Box Culverts

Wheel distribution specified in Article 12.11.2.3 need not be corrected for skew effects.

### 12.11.3—Strength Limit State

The provisions of Article 12.10.4.2.4a may be applied to the flexural strength design of slabs and walls of reinforced concrete cast-in-place and precast box culverts and reinforced cast-in-place arches.

### C12.11.3

Buried structures may be subject to high compressive thrust forces compared to most flexural members, and this thrust can result in a reduction in the required steel area. While influential in the reinforcement design, these thrust forces are not significant enough to warrant an individual analysis of compressive forces and flexural moments separately. Thus, Eq. 12.10.4.2.4a-1 may be used as a simplified, yet direct, method of determining the reinforcement areas for these structures.

### 12.11.4—Service Limit State

The provisions of Article 5.6.7 shall apply to crack width control in reinforced concrete cast-in-place and precast box culverts and reinforced cast-in-place arches.

### C12.11.4

Although high compressive thrust forces are usually considered in strength design, they are often ignored in service limit state design. The following equations, derived from ACI SP-3 can be used to consider the effect of thrust on stresses at the service limit state:

$$f_s = \frac{M_s + N_s\left(d - \frac{h}{2}\right)}{(A_s jid)} \qquad \text{(C12.11.4-1)}$$

in which:

$$e = M_s / N_s + d - h/2$$
$$i = 1/\left(1 - jd/e\right)$$
$$j = 0.74 + 0.1\left(e/d\right) \le 0.9$$

where:

$M_s$ = flexural moment at service limit state (kip-in./ft)
$N_s$ = axial thrust at service limit state (kip/ft)
$d$ = distance from compression face to centroid of tension reinforcement (in.)
$h$ = wall thickness (in.)
$A_s$ = area of reinforcement per unit length (in.$^2$/ft)
$f_s$ = reinforcement stress under service load condition (ksi)
$e/d$ min = 1.15 (dim.)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$i$ = coefficient for effect of axial force at service limit state, $f_s$
$j$ = coefficient for moment arm at service limit state, $f_s$

## 12.11.5—Safety Against Structural Failure

### 12.11.5.1—General

All sections shall be designed for the applicable factored loads specified in Table 3.4.1-1 at the strength limit state, except as modified herein. Shear in culverts shall be investigated in conformance with Article 5.12.7.3.

### 12.11.5.2—Design Moment for Box Culverts

Where monolithic haunches inclined at 45 degrees are specified, negative reinforcement in walls and slabs may be proportioned based on the flexural moment at the intersection of the haunch and uniform depth member. Otherwise, the provisions of Section 5 shall apply.

### 12.11.5.3—Minimum Reinforcement

*12.11.5.3.1—Cast-in-Place Structures*

Reinforcement shall not be less than that specified in Article 5.6.3.3 at all cross-sections subject to flexural tension, including the inside face of walls. Shrinkage and temperature reinforcement shall be provided near the inside surfaces of walls and slabs in accordance with Article 5.10.6.

*12.11.5.3.2—Precast Box Structures*

At all box culvert cross-sections subjected to flexural tension, the minimum reinforcement area shall be not less than 0.002 times the gross concrete area.

For top slabs of box culverts having less than 2.0 ft of cover, the bottom longitudinal reinforcement area shall be the greater of the distribution reinforcement required per Article 9.7.3.2 or 0.002 times the gross concrete area.

For all other longitudinal reinforcement, the minimum longitudinal reinforcement area shall not be less than 0.03 $in.^2/ft$ at each face.

Where the fabricated length exceeds 16.0 ft, the minimum reinforcement shall also meet the requirements of Article 5.10.6.

*C12.11.5.3.2*

The minimum requirement pertains to all reinforcement parallel to the span or rise on the inside and outside faces in walls and slabs of box culverts.

Designers suggested a minimum amount of reinforcement in consideration of handling, placement, backfilling, settlement, and long-term service life. For box culvert cross-sections subjected to flexural tension under typical in-service conditions, a ratio of reinforcement to gross concrete area of 0.002 is considered sufficient. Results from research performed on precast boxes at the University of Texas at Arlington showed no flexural tension in the direction perpendicular to the span of the box for wheel loads applied at the edge of a culvert segment. However, to protect the box culvert during the conditions listed above, some longitudinal steel is recommended. A minimum longitudinal reinforcement area of 0.03 $in.^2/ft$ at each face is considered adequate to meet these needs. This minimum requirement may be at least partially satisfied by the transverse wires when wire mesh reinforcement is used.

All rights reserved. Duplication is a violation of applicable law.

#### 12.11.5.4—Minimum Cover for Precast Box Structures

The provisions of Article 5.10.1 shall apply.

### 12.11.6—Construction and Installation

The contract documents shall require that construction and installation conform to Section 27, "Concrete Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.12—THERMOPLASTIC PIPES

### 12.12.1—General

The provisions herein shall apply to the structural design of buried thermoplastic pipe with solid, corrugated, or profile wall, manufactured of PE, PP, or PVC.

**C12.12.1**

These structures become part of a composite system comprised of the plastic pipe and the soil envelope.

The following specifications are applicable:

For PE:

- Solid Wall—ASTM F714,
- Corrugated—AASHTO M 294, and
- Profile—ASTM F894.

For PP:

- Corrugated—AASHTO M 330

For PVC:

- Solid Wall—AASHTO M 278 and
- Profile—AASHTO M 304.

### 12.12.2—Service Limit States

#### 12.12.2.1—General

The allowable maximum localized distortion of installed plastic pipe shall be limited based on the service requirements of the installation. The extreme fiber tensile strain shall not exceed the allowable long-term strain in Table 12.12.3.3-1. The net tension strain shall be the numerical difference between the bending tensile strain and ring compression strain.

**C12.12.2.1**

The allowable long-term strains should not be reached in pipes designed and constructed in accordance with this Specification. Deflections resulting from conditions imposed during pipe installation should also be considered in design.

#### 12.12.2.2—Deflection Requirement

Total deflection, $\Delta_t$, shall be less than the allowable deflection, $\Delta_A$, as follows:

$$\Delta_t \le \Delta_A \qquad (12.12.2.2\text{-}1)$$

where:

$\Delta_t$ = total deflection of pipe expressed as a reduction of the vertical diameter taken as positive for

**C12.12.2.2**

Deflection is controlled through proper construction in the field, and construction contracts should place responsibility for control of deflections on the contractor. However, feasibility of a specified installation needs to be checked prior to writing the project specifications.

The construction specifications set the allowable deflection, $\Delta_A$, for thermoplastic pipe at five percent as a generally appropriate limit. The Engineer may allow alternate deflection limits for specific projects if calculations using the design method in this section show

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

reduction of the vertical diameter and expansion of horizontal diameter. (in.)

$\Delta_A$ = total allowable deflection of pipe, reduction of vertical diameter (in.)

Total deflection, calculated using Spangler's expression for predicting flexural deflection in combination with the expression for circumferential shortening, shall be determined as:

$$\Delta_t = \frac{K_B\left(D_L P_{sp} + C_L P_L\right) D_o}{1000\left(E_p I_p / R^3 + 0.061\, M_s\right)} + \varepsilon_{sc} D \quad (12.12.2.2\text{-}2)$$

where:

$\varepsilon_{sc}$ = service compressive strain as specified in Article 12.12.3.10.1c

$D_L$ = deflection lag factor, a value of 1.5 is typical

$K_B$ = bedding coefficient, a value of 0.10 is typical

$P_{sp}$ = soil prism pressure evaluated at pipe springline as specified in Article 12.12.3.7 (psi)

$C_L$ = live load coefficient as specified in Article 12.12.3.5

$P_L$ = live load pressure as specified in Article 3.6.1.2.6

$D_o$ = outside diameter of pipe (in.) as shown in Figure C12.12.2.2-1

$E_p$ = short- or long-term modulus of pipe material as specified in Table 12.12.3.3-1 (ksi)

$I_p$ = moment of inertia of pipe profile per unit length of pipe (in.$^4$/in.)

$R$ = radius from center of pipe to centroid of pipe profile (in.) as shown in Figure C12.12.2.2-1

$D$ = diameter to centroid of pipe profile (in.) as shown in Figure C12.12.2.2-1

$M_s$ = secant constrained soil modulus, as specified in Article 12.12.3.5 (ksi)

Eq. 12.12.2.2-2 uses the constrained soil modulus, $M_s$, as the soil property. Note that the soil prism load is used as input, rather than the reduced load used to compute thrust.

This check should be completed to determine that the expected field deflection based on thrust and flexure is lower than the maximum allowable deflection for the project.

Thrust and hoop strain in the pipe wall are defined positive for compression.

There are no standard values for the deflection lag factor. Values from 1.0 to 6.0 have been recommended. The highest values are for installations with quality backfill and low initial deflections and do not generally control designs. A value of 1.5 provides some allowance for increase in deflection over time for installations with initial deflection levels of several percent.

The bedding coefficient, $K_B$, varies from 0.083 for full support to 0.110 for line support at the invert. Haunching is always specified to provide good support; however, it is still common to use a value of $K_B$ equal to 0.10 to account for inconsistent haunch support.

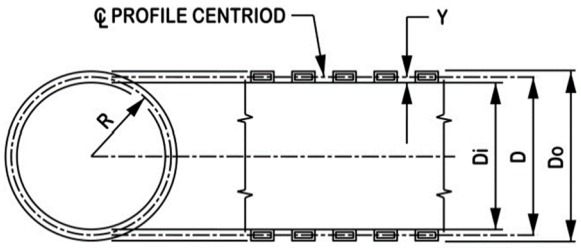

**Figure C12.12.2.2-1—Schematic for Thermoplastic Pipe Terms**

## 12.12.3—Safety Against Structural Failure

### 12.12.3.1—General

Buried thermoplastic culverts shall be investigated at the strength limit states for thrust, general and local buckling, and combined strain.

### C12.12.3.1

Total compressive strain in a thermoplastic pipe can cause yielding or buckling, and total tensile strain can cause cracking.

### 12.12.3.2—Section Properties

Section properties for thermoplastic pipe, including wall area, moment of inertia, and profile geometry should that the pipe meets all of the strength-limit-state requirements.

### C12.12.3.2

Historically, AASHTO bridge specifications have contained minimum values for the moment of inertia and wall area of thermoplastic pipe; however, these values

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

be determined from cut sections of pipe or obtained from the pipe manufacturer.

have been minimum values and are not meaningful for design. This is particularly so since provisions to evaluate local buckling were introduced in 2001. These provisions require detailed profile geometry that varies with manufacturer. Thus, there is no way to provide meaningful generic information on section properties. A convenient method for determining section properties for profile wall pipe is to make optical scans of pipe wall cross-sections and determine the properties with a computer drafting program.

**12.12.3.3—Chemical and Mechanical Requirements**

Mechanical properties for design shall be as specified in Table 12.12.3.3-1.

Except for buckling, the choice of either initial or long-term mechanical property requirements, as appropriate for a specific application, shall be determined by the Engineer. Investigation of general buckling shall be based on the value of modulus of elasticity that represents the design life of the project.

**C12.12.3.3**

Properties in Table 12.12.3.3-1 include "initial" and long-term values. No product standard requires determining the actual long-term properties; thus, there is some uncertainty in the actual values. However, pipe designed with the Table 12.12.3.3-1 values for 50-year modulus of elasticity have performed well, and the properties are assumed to be reasonably conservative. Estimated values for a modulus of elasticity for a 75-year design life have been estimated from relaxation tests on PVC, PP, and PE in parallel plate tests. The tests were conducted for over two years and show that the modulus of elasticity reduces approximately linearly with the logarithm of time. Further, with a log-linear extrapolation, the differences between 50-year and 75-year modulus values are very small. These values should be reasonably conservative, with the same reliability as the 50-year values. Pipe and thermoplastic resin suppliers should be asked to provide confirmation of long-term modulus values for any particular product. Values should meet or exceed those provided in Table 12.12.3.3-1. Where service life is in excess of 75 years, test data may be used for the desired life.

The service long-term tension strain limit and the factored compression strain limit in Table 12.12.3.3-1 need to be multiplied by the appropriate resistance factors to obtain the strain limits.

| Corrugated PP Pipe – AASHTO M 330 | Requirements in M 330 | 2.5 | 3.7 | 3.5 | 175 | 1.0 | 29 | 1.0 | 28 |

### 12.12.3.4—Thrust

Loads on buried thermoplastic pipe shall be based on the soil prism load, modified as necessary to consider the effects of pipe–soil interaction. Calculations shall consider the duration of a load when selecting pipe properties to be used in design. Live loads need not be considered for the long-term loading condition.

### C12.12.3.4

Because of the time-dependent nature of thermoplastic pipe properties, the load will vary with time.

Time of loading is an important consideration for some types of thermoplastic pipe. Live loads and occasional flood conditions are normally considered short-term loads. Earth loads or permanent high groundwater are normally considered long-term loads.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.12.3.5—Factored and Service Loads

The factored thrust shall be taken as:

$$T_u = \left[\eta_{EV}\left(\gamma_{EV}K_{\gamma E}K_2 VAF\,P_{sp} + \gamma_{WA}P_w\right) + \eta_{LL}\gamma_{LL}P_L\;C_L F_1 F_2\right]\frac{D_o}{2} \quad (12.12.3.5\text{-}1)$$

The service thrust shall be taken as:

$$T_s = \left[K_2 VAF\,P_{sp} + P_L\;C_L\;F_1F_2 + P_w\right]\frac{D_o}{2} \quad (12.12.3.5\text{-}2)$$

in which:

$$VAF = 0.76 - 0.71\left(\frac{S_H - 1.17}{S_H + 2.92}\right) \quad (12.12.3.5\text{-}3)$$

$$S_H = \frac{\phi_s M_s R}{E_p A_g} \quad (12.12.3.5\text{-}4)$$

$$C_L = \frac{\ell_w}{D_o} \le 1.0 \quad (12.12.3.5\text{-}5)$$

$$F_1 = \frac{0.75D_o}{\ell_w} \ge F_{\min} \quad (12.12.3.5\text{-}6)$$

$$F_{\min} = \frac{15}{D_i} \ge 1 \quad (12.12.3.5\text{-}7)$$

$$F_2 = \frac{0.95}{1 + 0.6S_H} \quad (12.12.3.5\text{-}8)$$

where:

$T_u$ = factored thrust per unit length (lb/in.)
$T_s$ = service thrust per unit length (lb/in.)
$P_L$ = live load pressure as specified in Article 3.6.1.2.6
$\ell_w$ = live load distribution width in the circumferential direction as specified in Article 3.6.1.2.6
$K_{\gamma E}$ = installation factor typically taken as 1.5 to provide traditional safety. Use of a value less than 1.5 requires additional monitoring of the installation during construction and provisions for such monitoring shall be provided on the contract documents.

### C12.12.3.5

For η factors, refer to Article 12.5.4 regarding assumptions about redundancy for earth loads and live loads.

The factor $K_2$ is introduced to consider variation in thrust around the circumference, which is necessary when combining thrust with moment or thrust due to earth and live load under shallow fill. $K_2$ is set at 1.0 to determine thrust at the springline and 0.6 to determine thrust at the crown. The term $P_L$ is also modified for this reason in later sections.

Figure C3.11.3-1 shows the effect of groundwater on the earth pressure. $P_{sp}$ does not include the hydrostatic pressure. $P_{sp}$ is the pressure due to the weight of soil above the pipe and should be calculated based on the wet density for soil above the water table and based on the buoyant density for soil below the water table. See Table 3.5.1-1 for common unit weights.

In computing $\ell_w$, add axle spacing (and increase total live load) if depth is sufficient for axle loads to interact.

The factor $K_{\gamma E}$ is introduced to provide the same safety level as traditionally used for thermoplastic culverts. Designers may consider using values of $K_{\gamma E}$ as low as 1.0 provided that procedures are implemented to ensure compliance with construction specifications. For culvert designs completed with an installation factor less than 1.5, the designer is required to specify additional minimum performance measures such as testing, monitoring, construction controls, and backfill requirements including active monitoring of the backfill gradation and compaction (see Article 30.7.4 of the *AASHTO LRFD Bridge Construction Specifications)*. The construction controls include deflection measurements and shall require the Contractor to submit and get approval from the Owner's Engineer for his/her construction plan to be used to achieve the more stringent

All rights reserved. Duplication is a violation of applicable law.

performance measures which allowed for the use of a smaller installation factor in the design. Backfill placement and monitoring shall be done at levels along the side of the culvert and includes measurement of change in vertical pipe diameter when the backfill reaches the top of the pipe. As the backfill nears the top of pipe the vertical pipe diameter should be greater than the vertical diameter prior to backfilling, but not more than three percent greater than the vertical diameter prior to backfilling. When construction controls are implemented and the project specifications call for the total length of the pipe to be inspected and the vertical and horizontal deflection be measured no sooner than 30 days after backfill/embankment is completed, a value of $K_{\gamma E}$ =1.0 may be used for design.

$K_2$ = coefficient to account for variation of thrust around the circumference
= 1.0 for thrust at the springline
= 0.6 for thrust at the crown

$VAF$ = vertical arching factor

The use of the vertical arching factor is based on the behavior, demonstrated by Burns and Richard (1964), that pipe with high hoop-stiffness ratios ($S_H$, ratio of soil stiffness to pipe hoop stiffness) carry substantially less load than the weight of the prism of soil directly over the pipe. This behavior was demonstrated experimentally by Hashash and Selig (1990) and analytically by Moore (1995). McGrath (1999) developed the simplified form of the equation presented in this Section.

The *VAF* approach is only developed for the embankment load case. No guidance is currently available to predict the reduced loads on pipe in trench conditions. The only trench load theory proposed for flexible pipe was that by Spangler, which does not have good guidance on selection of input parameters. It is conservative to use the *VAF* approach as presented for embankments.

$S_H$ = hoop stiffness factor

If evaluating the short-term load condition, then use the initial modulus of elasticity to compute $S_H$. Similarly, if evaluating the long-term loading condition, then use the long-term modulus of elasticity to compute $S_H$.

$P_w$ = hydrostatic water pressure at the springline of the pipe (psi)

$C_L$ = live load distribution coefficient

$\eta_{EV}$ = load modifier as specified in Article 1.3.2, as it applies to vertical earth loads on culverts

$\gamma_{EV}$ = load factor for vertical pressure from dead load of earth fill, as specified in Article 3.4.1

$P_{sp}$ = soil prism pressure (EV), evaluated at pipe springline (psi)

$\gamma_{WA}$ = load factor for hydrostatic pressure, as specified in Article 3.4.1

$\eta_{LL}$ = load modifier as specified in Article 1.3.2, as it applies to live loads on culverts

$\gamma_{LL}$ = load factor for live load, as specified in Article 3.4.1

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$P_L$ = live load pressure ($LL$) with dynamic load allowance (psi)
$\phi_s$ = resistance factor for soil stiffness
$M_s$ = secant constrained soil modulus as specified in Table 12.12.3.5-1 or Table 12.12.3.5-3 (ksi)
$R$ = radius from center of pipe to centroid of pipe profile (in.)
$E_p$ = short- or long-term modulus of pipe material as specified in Table 12.12.3.3-1 (ksi)
$A_g$ = gross area of pipe wall per unit length of pipe (in.$^2$/in.)
$D_o$ = outside diameter of pipe (in.)
$LLDF$ = live load distribution factor through earth fills in Article 3.6.1.2.6

In the absence of site-specific data, the secant constrained soil modulus, $M_s$, may be selected from Table 12.12.3.5-1 based on the backfill type and density and the geostatic earth pressure, $P_{sp}$. Linear interpolation between soil stress levels may be used for the determination of $M_s$. If crushed stone backfill is used, the secant constrained modulus, $M_s$, may be selected from Table 12.12.3.5-3.

For culverts in embankment or wide trench installations under depths of fill up to 10.0 ft, the secant constrained soil modulus, $M_s$, selected from Table 12.12.3.5-1 or Table 12.12.3.5-3 shall be based on the backfill type and density conditions for a width of one-half diameter on each side of the culvert, but never less than 18.0 in. on each side of the culvert. For culverts under depths of fill greater than 10.0 ft, the secant constrained soil modulus, $M_s$, selected shall be based on the backfill type and density conditions for a width of one diameter on each side of the culvert.

The term $\phi_s$ appears in Eq. 12.12.3.5-4 to account for variability in backfill compaction. A lower level of compaction increases the applied thrust force on the pipe.

For selecting values of the constrained soil modulus, $M_s$, prior editions of these Specifications contained the commentary "Suggested practice is to design for a standard Proctor backfill density five percent less than specified by the contract documents." This statement is not considered necessary with the addition of post-construction inspection guidelines to the *AASHTO LRFD Bridge Construction Specifications*, which should provide reasonable assurance that the design condition is achieved.

For culverts in trench installations under depths of fill greater than 10.0 ft, evaluation of the values of $M_s$ for in-situ soil for a width one diameter either side of the pipe is not necessary, provided the in-situ soil has adequate vertical and lateral stiffness. Stable trench walls during the excavation process are predictive of adequate vertical and lateral stiffness.

Installation in narrow trenches reduces the vertical load, provided vertical stiffness of the soil is adequate to carry the load that is distributed around the pipe due to arching, as represented by the vertical arching factor ($VAF$) in the design method and adequate space is preserved at the side of the pipe to place and compact backfill. The minimum trench widths provided in the *AASHTO LRFD Bridge Construction Specifications* are set to provide adequate space. Narrow trenches yield a desirable level of conservatism, since the transfer of the load to in-situ trench wall is not considered in flexible pipe design.

If the structural backfill material is crushed stone, then the secant constrained soil modulus, $M_s$, values shown in Table 12.12.3.5-3 may be used. If an aggregate other than granite, limestone, or quartz is used, or if the aggregate type is unknown, the constrained soil modulus values for crushed limestone may be conservatively applied. These constrained modulus values are independent of burial depth. While it is not common practice to monitor density of crushed stone backfills, experience has found that a modest compaction effort improves culvert performance and allows the use of the compacted values.

The width of structural backfill is an important consideration when the in situ soil in the trench wall or the embankment fill at the side of the structural backfill is soft. Currently, only the American Water Works Association (AWWA)'s *Manual of Water Supply Practices—M45* addresses this issue.

The constrained modulus is the slope of the secant from the origin of the curve to a point on the curve corresponding to the soil prism pressure, $P_{sp}$, Figure C12.12.3.5-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The constrained modulus may also be determined experimentally using the stress–strain curve resulting from a uniaxial strain test on a sample of soil compacted to the field-specified density.

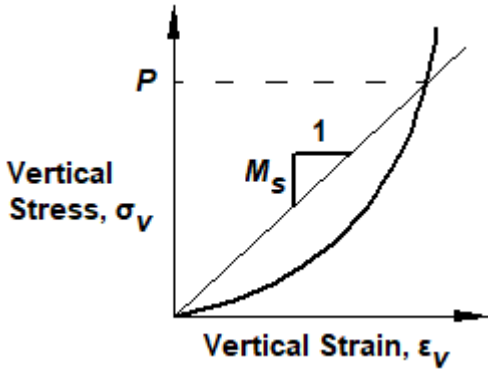

**Figure C12.12.3.5-1—Schematic One-Dimensional Stress–Strain Curve of Soil Backfill**

**Table 12.12.3.5-1—$M_s$ Based on Soil Type and Compaction Condition**

| $P_{sp}$ Stress Level (psi) | Sn-100 (ksi) | Sn-95 (ksi) | Sn-90 (ksi) | Sn-85 (ksi) |
|---|---|---|---|---|

**Table 12.12.3.5-2—Equivalent ASTM and AASHTO Soil Classifications**

| Basic Soil Type (1) | ASTM D2487 | AASHTO M 145 |
|---|---|---|
| Sn (Gravelly sand, SW) | SW, SP (2) GW, GP sands and gravels with 12% or less fines | A-1, A-3 (2) |
| Si (Sandy silt, ML) | GM, SM, ML also GC and SC with less than 20% passing a No. 200 sieve | A-2-4, A-2-5, A-4 |
| Cl (Silty clay, CL) | CL, MH, GC, SC also GC and SC with more than 20% passing a No. 200 sieve | A-2-6, A-2-7, A-5, A-6 |

1. The soil classification listed in parentheses is the type that was tested to develop the constrained soil modulus values in Table 12.12.3.5-1. The correlations to other soil types are approximate.
2. Uniformly graded materials with an average particle size smaller than a No. 40 sieve shall not be used as backfill for thermoplastic culverts unless specifically allowed in the contract documents and special precautions are taken to control moisture content and monitor compaction levels.

**Table 12.12.3.5-3—Constrained Modulus, $M_s$, Values for Crushed Stone Backfill Materials**

| Aggregate | Maximum Particle Size (in.) | Constrained Modulus, $M_s$ (ksi) | |
|---|---|---|---|
| | | Dumped | Compacted |
| Granite | 0.75 | 7.000 | 8.500 |
| | 1.50 | 3.500 | 5.000 |
| Limestone | 0.75 | 3.500 | 5.500 |
| Quartz | 0.75 | 5.500 | 7.500 |

### 12.12.3.6—Handling and Installation Requirements

The flexibility factor, *FF*, in./kip shall be taken as:

$$FF = \frac{S^2}{EI} \qquad (12.12.3.6\text{-}1)$$

where:

$I$ = moment of inertia (in.$^4$/in.)
$E$ = initial modulus of elasticity (ksi)
$S$ = diameter of pipe (in.)

The flexibility factor, *FF*, shall be limited as specified in Article 12.5.6.3.

### 12.12.3.7—Soil Prism

The soil prism load shall be calculated as a pressure representing the weight of soil above the pipe springline. The pressure shall be calculated for three conditions:

### C12.12.3.7

The soil prism load and vertical arching factor, *VAF*, serve as a common reference for the load on all types of pipe.

The soil prism calculation needs to consider the unit weight of the backfill over the pipe. Use the wet unit weight above the water table and the buoyant unit weight below the water table. In cases where the water table fluctuates, multiple conditions may need to be evaluated.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- If the water table is above the top of the pipe and at or above the ground surface:

$$P_{sp} = \frac{\left(H + 0.11\frac{D_o}{12}\right)\gamma_b}{144} \qquad (12.12.3.7\text{-}1)$$

- If the water table is above the top of the pipe and below the ground surface:

$$P_{sp} = \frac{1}{144}\left[\begin{array}{c}\left[\left(H_W - \frac{D_o}{24}\right) + 0.11\frac{D_o}{12}\right]\gamma_b + \\ \left[H - \left(H_w - \frac{D_o}{24}\right)\right]\gamma_s\end{array}\right] \qquad (12.12.3.7\text{-}2)$$

- If the water table is below the top of the pipe:

$$P_{sp} = \frac{\left(H + 0.11\frac{D_o}{12}\right)\gamma_s}{144} \qquad (12.12.3.7\text{-}3)$$

where:

$P_{sp}$ = soil prism pressure (EV), evaluated at pipe springline (psi)
$D_o$ = outside diameter of pipe (in.)
$\gamma_b$ = unit weight of buoyant soil (lb/ft$^3$)
$H$ = depth of fill over top of pipe (ft)
$H_w$ = depth of water table above springline of pipe (ft)
$\gamma_s$ = wet unit weight of soil (lb/ft$^3$)

Figure C3.11.3-1 shows the effect of groundwater on the earth pressure. See Table 3.5.1-1 for common unit weights.

**12.12.3.8—Hydrostatic Pressure**

The pressure due to ground water shall be calculated as:

$$P_w = \frac{\gamma_w\ K_{wa}\ H_w}{144} \qquad (12.12.3.8\text{-}1)$$

where:

$P_w$ = hydrostatic water pressure at the springline of the pipe (psi)
$\gamma_w$ = unit weight of water (lb/ft$^3$)
$K_a$ = factor for uncertainty in level of groundwater table

**C12.12.3.8**

Hydrostatic loading due to external water pressure should be calculated in all cases where water table may be above the pipe springline at any time. This load contributes to hoop thrust but does not affect deflection.

There is often uncertainty in the level of the groundwater table and its annual variations. The designer may use the factor $K_{wa}$ with values up to 1.3 to account for

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

this uncertainty or may select conservative values of $H_w$ with a lower value of $K_{wa}$ but not less than 1.

**12.12.3.9—Live Load**

The provisions of Article 12.6.1 shall apply.

**12.12.3.10—Wall Resistance**

*12.12.3.10.1—Resistance to Axial Thrust*

*12.12.3.10.1a—General*

Elements of profile wall pipe shall be designed to resist local buckling. To determine local buckling resistance, profile-wall pipe geometry shall be idealized as specified herein and an effective area determined in accordance with the following provisions.

*12.12.3.10.1b—Local Buckling Effective Area*

For the determination of buckling resistance, profile wall pipe shall be idealized as straight elements. Each element shall be assigned a width based on the clear distance between the adjoining elements and a thickness based on the thickness at the center of the element. The idealization of a typical corrugated profile should be based on the approximation in Figure 12.12.3.10.1b-1.

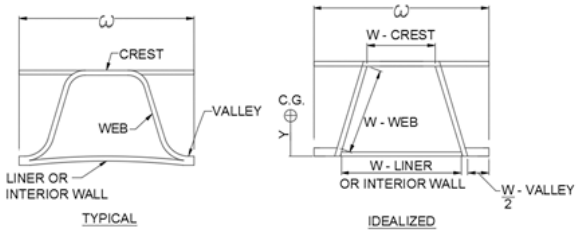

**Figure 12.12.3.10.1b-1—Typical and Idealized Cross-section of Profile Wall Pipe**

To evaluate the resistance to axial thrust, the area of the profile shall be reduced to an effective area, $A_{eff}$, for local buckling effects. The effective area of the profile shall be determined by subtracting the ineffective area of each element from the gross section area, as:

$$A_{eff} = A_g - \frac{\sum(w - b_e)t}{\omega} \qquad (12.12.3.10.1b\text{-}1)$$

in which:

$$b_e = \rho w \qquad (12.12.3.10.1b\text{-}2)$$

$$\rho = \frac{\left(1 - \frac{0.22}{\lambda}\right)}{\lambda} \qquad (12.12.3.10.1b\text{-}3)$$

*C12.12.3.10.1b*

To complete the local buckling calculations, the profile is idealized into a group of rectangular elements. To complete the idealization, it should include:

- The actual total area.
- If the crest element is curved, it should be idealized at the centroid of the curvature. The idealized element need not touch the idealized webs.

See McGrath et al. (2009) for guidance on other profile types.

The resistance to local buckling is based on the effective width concept used by the cold formed steel industry. This theory assumes that even though buckling is initiated in the center of a plate element, the element still has substantial post-buckling strength at the edges where the element is supported. This concept is demonstrated in Figure C12.12.3.10.1b-1.

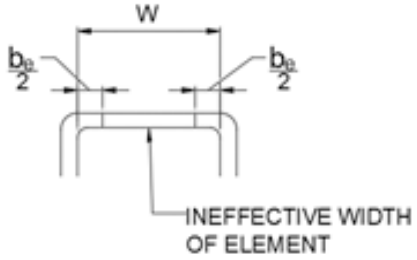

**Figure C12.12.3.10.1b-1—Effective Width Concept**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$\lambda = \left(\frac{w}{t}\right)\sqrt{\frac{\varepsilon_{yc}}{k}} \geq 0.673 \qquad (12.12.3.10.1b\text{-}4)$$

The local buckling evaluation reduces the capacity of pipe wall sections with high ratios of width to thickness.

The calculations in Eqs. 12.12.3.10.1b-1 to 12.12.3.10.1b-4 must be repeated for each element in the idealized profile.

where:

$A_{eff}$ = effective area of pipe wall per unit length of pipe (in.$^2$/in.)
$b_e$ = element effective width (in.)
$\rho$ = effective width factor
$\lambda$ = slenderness factor
$\omega$ = spacing of corrugation (in.) as specified in Figure 12.12.3.10.1b-1
$\varepsilon_{yc}$ = factored compressive strain limit as specified in Table 12.12.3.3-1
$A_g$ = gross area of pipe wall per unit length of pipe (in.$^2$/in.)
$t$ = thickness of element (in.)
$w$ = total clear width of element between supporting elements (in.)
$k$ = plate buckling coefficient, k=4 for supported elements, $k = 0.43$ for unsupported elements, such as free standing ribs

The plate buckling coefficient is analogous to the effective length factor, $k$, in column buckling.

As an alternate to determining the effective area by the calculation procedure presented above, the results of the stub compression test, AASHTO T 341, may be used, in which case the effective area, $A_{eff}$, shall satisfy:

The stub compression test has been incorporated as a requirement into AASHTO product standards M 294, M 330, and M 304. The test data should be readily available from manufacturers and quality control tests.

$$A_{eff} = \frac{P_{st} K_t}{F_u} \leq A_g \qquad (12.12.3.10.1b\text{-}5)$$

in which:

$P_{st}$ = stub compression capacity from T 341 (kip/in.)
$K_t$ = time factor as specified in Table 12.12.3.10.1b-1
$F_u$ = material yield strength for design load duration (ksi)

**Table 12.12.3.10.1b-1—Time Factor**

| Time Period | PE | PP | PVC |
|---|---|---|---|
| Initial | 0.9 | 0.9 | 0.95 |
| 50 yr | 0.3 | 0.3 | 0.6 |
| 75 yr (est.) | 0.25 | 0.25 | 0.5 |

*12.12.3.10.1c—Compression Strain*

The factored compressive strain due to factored thrust, $\varepsilon_{uc}$, and the service compressive strain due to service thrust, $\varepsilon_{sc}$, shall be taken as:

$$\varepsilon_{uc} = \frac{T_u}{1{,}000\left(A_{eff} E_p\right)} \qquad (12.12.3.10.1c\text{-}1)$$

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$\varepsilon_{sc} = \frac{T_s}{1{,}000\left(A_{eff}E_p\right)} \qquad (12.12.3.10.1c\text{-}2)$$

where:

$\varepsilon_{uc}$ = factored compressive strain due to thrust
$\varepsilon_{sc}$ = service compressive strain due to thrust
$T_u$ = factored thrust per unit length (lb/in.)
$T_s$ = service thrust per unit length (lb/in.)
$A_{eff}$ = effective area of pipe wall per unit length of pipe (in.$^2$/in.)
$E_p$ = short-term modulus for short-term loading or long-term modulus of pipe material for long-term loading as specified in Table 12.12.3.3-1 (ksi)

*12.12.3.10.1d—Thrust Strain Limits*

The factored compression strain due to thrust, $\varepsilon_{uc}$, shall satisfy:

$$\varepsilon_{uc} \le \phi_T \varepsilon_{yc} \qquad (12.12.3.10.1d\text{-}1)$$

where:

$\varepsilon_{uc}$ = factored compressive strain due to thrust
$\phi_T$ = resistance factor for thrust effects
$\varepsilon_{yc}$ = factored compression strain limit of the pipe wall material as specified in Table 12.12.3.3-1

*12.12.3.10.1e—General Buckling Strain Limits*

The factored compression strain due to thrust, incorporating local buckling effects, $\varepsilon_{uc}$, shall satisfy:

$$\varepsilon_{uc} \le \phi_{bck} \varepsilon_{bck} \qquad (12.12.3.10.1e\text{-}1)$$

The nominal strain capacity for general buckling of the pipe shall be determined as:

$$\varepsilon_{bck} = \frac{1.2C_n\left(E_pI_p\right)^{\frac{1}{3}}}{A_{eff}E_p}\left[\frac{\phi_s M_s\left(1-2\nu\right)}{\left(1-\nu\right)^2}\right]^{\frac{2}{3}} R_h \qquad (12.12.3.10.1e\text{-}2)$$

in which:

$$R_h = \frac{11.4}{11+\frac{D}{12H}} \qquad (12.12.3.10.1e\text{-}3)$$

where:

$\varepsilon_{uc}$ = factored compressive strain due to thrust
$\phi_{bck}$ = resistance factor for global buckling
$\varepsilon_{bck}$ = nominal strain capacity for general buckling

*C12.12.3.10.1e*

The equations for global resistance presented here are a conservative simplification of the continuum buckling theory presented by Moore (1990). Detailed analysis using the full theory may be applied in lieu of the calculations in this section.

The term $\phi_s$ appears in this expression for $\varepsilon_{bck}$ to account for backfills compacted to levels below that

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

specified in the design. Lower levels of compaction increases the thrust force in the pipe.

For designs meeting all other requirements of these specifications and the *AASHTO LRFD Bridge Construction Specifications*, the correction for backfill soil geometry, $R_h$, is equal to value at left.

$R_h$ = correction factor for backfill soil geometry

The complete theory proposed by Moore (1990) provides variations in $R_h$ that consider nonuniform backfill support. In the extreme case where the width of structural backfill at the side of the culvert is 0.1 times the span and the modulus of the soil outside of the structural backfill is 0.1 times the modulus of the backfill, then:

$$R_h = \frac{20}{56 + \frac{D}{12H}} \qquad \text{(C12.12.3.10.1e-1)}$$

$C_n$ = calibration factor to account for nonlinear effects = 0.55
$E_p$ = short- or long-term modulus of pipe material as specified in Table 12.12.3.3-1 (ksi)
$I_p$ = moment of inertia of pipe profile per unit length of pipe (in.$^4$/in.)
$A_{eff}$ = effective area of pipe profile per unit length of pipe (in.$^2$/in.)
$\phi_s$ = resistance factor for soil pressure
$M_s$ = secant constrained soil modulus as specified in Table 12.12.3.5-1 (ksi)
$\nu$ = Poisson's ratio of soil

Poisson's ratio is used to convert the constrained modulus of elasticity to the plane strain modulus. Values for Poisson's ratio of soils are provided in many geotechnical references. One reference is Selig (1990).

$D$ = diameter to centroid of pipe profile (in.)
$H$ = depth of fill over top of pipe (ft)

*12.12.3.10.2—Bending and Thrust Strain Limits*

*12.12.3.10.2a—General*

To ensure adequate flexural capacity the combined strain at the extreme fibers of the pipe profile must be evaluated at the allowable deflection limits against the limiting strain values.

*12.12.3.10.2b—Combined Strain*

*C12.12.3.10.2b*

If summation of axial strain, $\varepsilon_{uc}$, and bending strain, $\varepsilon_f$, produces tensile strain in the pipe wall, the combined strain at the extreme fiber where flexure causes tension shall satisfy:

$$\varepsilon_f - \varepsilon_{uc} < \phi_f \varepsilon_{yt} \qquad \text{(12.12.3.10.2b-1)}$$

The combined strain at the extreme fiber where flexure causes compression shall satisfy:

$$\varepsilon_f + \varepsilon_{uc} < \phi_T \left(1.5\varepsilon_{yc}\right) \qquad \text{(12.12.3.10.2b-2)}$$

The criteria for combined compressive strain are based on limiting local buckling. A higher strain limit is allowed for combined strains because under bending, the web elements have a low stress near the centroid of the element and are thus unlikely to buckle. Thus the unbuckled web elements increase the stability of the crest and valley elements.

The strain limit for combined compression strain is 50 percent higher than that for hoop compression alone because the web elements, which experience low strains due to bending, are not likely to buckle, thus increasing the stability of elements near the crest and valley. While this behavior would be more accurately modeled as an

All rights reserved. Duplication is a violation of applicable law.

where:

$\varepsilon_f$ = factored strain due to flexure
$\varepsilon_{uc}$ = factored compressive strain due to thrust
$\varepsilon_{yt}$ = service long-term tension strain limit of the pipe wall material as specified in Table 12.12.3.3-1
$\phi_f$ = resistance factor for flexure
$\phi_T$ = resistance factor for thrust
$\varepsilon_{yc}$ = factored compression strain limit of the pipe wall material as specified in Table 12.12.3.3-1

In the absence of a more-detailed analysis, the flexural strain may be determined based on the empirical relationship between strain and deflection as:

$$\varepsilon_f = \gamma_{EV} D_f \left(\frac{c}{R}\right)\left(\frac{\Delta_f}{D}\right) \qquad (12.12.3.10.2b\text{-}3)$$

in which:

$$\Delta_f = \Delta_A - \varepsilon_{sc} D \qquad (12.12.3.10.2b\text{-}4)$$

where:

$\varepsilon_f$ = factored strain due to flexure
$\varepsilon_{sc}$ = service compression strain due to thrust
$\Delta_f$ = reduction of vertical diameter due to flexure (in.)
$\gamma_{EV}$ = load factor for vertical pressure from dead load of earth fill, as specified in Article 3.4.1
$D_f$ = shape factor as specified in Table 12.12.3.10.2b-1. The shape factors for corrugated PE and PP pipes can be reduced by 1.0 from the table values to account for the effect of the low hoop stiffness ratio.
$c$ = the larger of the distance from neutral axis of profile to the extreme innermost or outermost fiber (in.)
$R$ = radius from center of pipe to centroid of pipe profile (in.)
$D$ = diameter to centroid of pipe profile (in.)
$\Delta_A$ = total allowable deflection of pipe, reduction of vertical internal diameter (in.)

increase in the $k$ factor of Eq. 12.12.3.10.1b-4, the increase in the limiting strain is considered adequate for this simplified design method.

For thrust capacity, the section is limited by consideration of hoop compression capacity alone. The check of combined compression strain, hoop plus bending, is used to limit the allowable pipe deflection.

Elements subjected primarily to bending (such as a web element in Figure 12.12.3.10.1b-1 when the pipe is deflected) are not highly stressed near the centroid, where buckling initiates, and theoretical $k$ factors for plates in bending are greater than 20. To simplify the analysis for combined bending and thrust, elements, such as the web whose centroid is within $c/3$ of the centroid of the entire profile wall, may be analyzed only for the effect of hoop compression strains. That is, increases in strain due to bending may be ignored.

Past practice has used tensile strain limits specified in Table 12.12.3.3-1, with no guidance on ultimate strain limits. For purposes of design calculations, assume that ultimate tensile strain capacity is 50 percent greater than the service capacities provided in Table 12.12.3.3-1.

A higher strain limit is allowed under combined bending and compression. This increase is permitted because the web element under flexure has a low stress at the center of the element, reducing the likelihood of buckling, and allowing it to provide more stability to the crest and valley elements.

Flexural strains are always taken as positive. The service compressive strain is used for determination of the factored strain due to flexure instead of the factored compressive strain. The use of the factored compressive strain would result in an unconservative flexural strain demand.

The empirical shape factor is used in the design of fiberglass pipe and is presented in AWWA *Manual of Water Supply Practices—M45*. It demonstrates that bending strains are highest in low stiffness pipe backfilled in soils that require substantial compactive effort (silts and clays), and is lowest in high stiffness pipe backfilled in soils that require little compactive effort (sands and gravels).

Table 12.12.3.10.2b-1 does not cover all possible backfills and density levels. Designers should interpolate or extrapolate the Table as necessary for specific projects.

More detailed analyses must consider the likelihood of inconsistent soil support to the pipe in the haunch zone, and of local deformations during placement and compaction of backfill.

Bending strains typically cannot be accurately predicted during design due to variations in backfill materials and compactive effort used during installation. Installation deflection limits are specified in the construction specifications to assure that design parameters are not exceeded.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The deflection design limit is five percent reduction of the vertical diameter as specified in the construction specification. The pipe must be designed to permit this deflection, unless extraordinary measures are specified in contract documents to minimize compactive effort and to control deflections.

The *AASHTO LRFD Bridge Construction Specifications* currently restrict the allowable total vertical deflection to five percent.

**Table 12.12.3.10.2b-1—Shape Factors, $D_f$, based on Pipe Stiffness, Backfill, and Compaction Level**

| Pipe Stiffness ($F/\Delta_y$, ksi) $= EI / 0.149\ R^3$ | Pipe Zone Embedment Material and Compaction Level | | | |
|---|---|---|---|---|
| | Gravel (1) | | Sand (2) | |
| | Dumped to Slight (3) | Moderate to High (4) | Dumped to Slight (3) | Moderate to High (4) |
| 0.009 | 5.5 | 7.0 | 6.0 | 8.0 |
| 0.018 | 4.5 | 5.5 | 5.0 | 6.5 |
| 0.036 | 3.8 | 4.5 | 4.0 | 5.5 |
| 0.072 | 3.3 | 3.8 | 3.5 | 4.5 |

1. GW, GP, GW–GC, GW–GM, GP–GC, and GP–GM per ASTM D2487 (includes crushed rock)
2. SW, SP, SM, SC, GM, and GC or mixtures per ASTM D2487
3. <85% of maximum dry density per AASHTO T 99, < 40% relative density (ASTM D4253 and D4254)
4. ≥85% of maximum dry density per AASHTO T 99, ≥ 40% relative density (ASTM D4253 and D4254)

### 12.12.4—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 30, "Thermoplastic Culverts," of the *AASHTO LRFD Bridge Construction Specifications*.

## 12.13—STEEL TUNNEL LINER PLATE

### 12.13.1—General

The provisions of this Article shall apply to the structural design of steel tunnel liner plates. Construction shall conform to Section 25, "Steel and Concrete Tunnel Liners," of the *AASHTO LRFD Bridge Construction Specifications*.

The tunnel liner plate may be two-flange, fully corrugated with lapped longitudinal seams or four-flange, partially corrugated with flanged longitudinal seams. Both types shall be bolted together to form annular rings.

**C12.13.1**

The supporting capacity of a nonrigid tunnel lining, such as a steel liner plate, results from its ability to deflect under load, so that side restraint developed by the lateral resistance of the soil constrains further deflection. Thus, deflection tends to equalize radial pressures and to load the tunnel liner as a compression ring.

### 12.13.2—Loading

The provisions for earth loads given in Article 3.11.5 shall not apply to tunnels.

**C12.13.2**

The earth load to be carried by the tunnel liner is a function of the type of soil. In granular soil with little or no cohesion, the load is a function of the angle of internal friction of the soil and the diameter of the tunnel. In cohesive soils such as clays, the load to be carried by the tunnel liner is dependent on the shearing strength of the soil above the roof of the tunnel.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.13.2.1—Earth Loads

The provisions of Article 12.4.1 shall apply. When more refined methods of soil analysis are not employed, the earth pressure may be taken as:

$$W_E = C_{dt}\gamma_s S \qquad (12.13.2.1\text{-}1)$$

where:

$C_{dt}$ = load coefficient for tunnel installation specified in Figure 12.13.2.1-1
$\gamma_s$ = total unit weight of soil (kcf)
$W_E$ = earth pressure at the crown (ksf)
$S$ = tunnel diameter or span (ft)

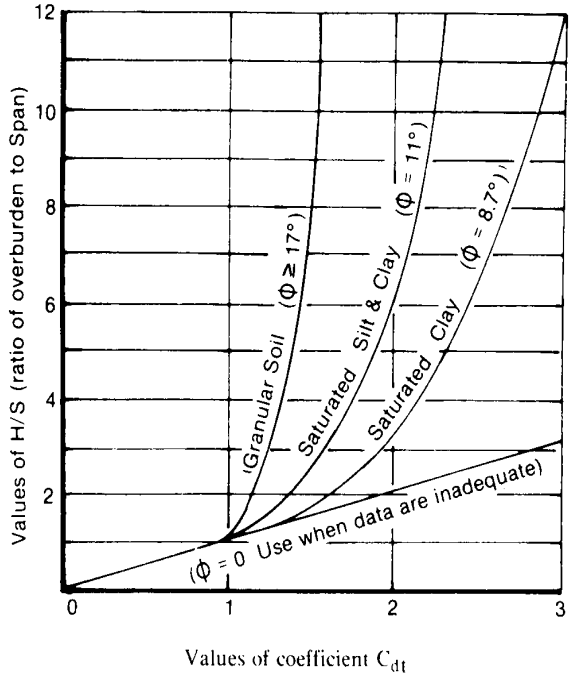

**Figure 12.13.2.1-1—Diagram for Coefficient $C_{dt}$ for Tunnel in Soil**

in which:

$H$ = height of soil over top of tunnel (ft)

### C12.13.2.1

Eq. 12.13.2.1-1 is a form of the Marston formula. It proportions the amount of total overburden pressure acting on the tunnel based on the internal friction angle of the soil to be tunneled.

In the absence of adequate borings and soil tests, use $\phi_f = 0$ when calculating $W_E$.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 12.13.2.2—Live Loads

The provisions of Article 12.6.1 shall apply.

#### 12.13.2.3—Grouting Pressure

If the grouting pressure is greater than the computed design load, the design load, $W_T$, on the tunnel liner shall be the grouting pressure.

### 12.13.3—Safety Against Structural Failure

#### 12.13.3.1—Section Properties

Steel tunnel liner plate shall meet the minimum requirements of Table 12.13.3.1-1 for cross-sectional properties, Table 12.13.3.1-2 for seam strength, and Table 12.13.3.1-3 for mechanical properties.

#### 12.13.3.2—Wall Area

The requirements of Articles 12.7.2.2 and 12.7.2.3 shall apply using effective area from Table 12.13.3.1-1.

#### 12.13.3.3—Buckling

The requirements of Article 12.7.2.4 shall apply, except that the soil stiffness factor, $k$, may vary from 0.22 to 0.44 depending upon the quality and extent of the backpacking material used.

**C12.13.3.3**

Wall buckling is a function of the stiffness, $k$, of the surrounding soil bearing on the plates. Where portland cement grouting or quality backpacking (meeting the requirements of Section 25, "Steel and Concrete Tunnel Liners," of the *AASHTO LRFD Bridge Construction Specifications*) material fill the void outside the plates, $k = 0.22$ is applicable. For other soils or in-situ backpacking material, $k = 0.44$ is suggested. Where tunneled soils slough or voids are left in the backpacking, additional consideration as to the value of $k$ may be required.

#### 12.13.3.4—Seam Strength

The requirements of Article 12.7.2.5 shall apply.

#### 12.13.3.5—Construction Stiffness

Construction stiffness shall be indicated by a construction stiffness factor as:

$$C_S = \frac{EI}{S^2} \qquad (12.13.3.5\text{-}1)$$

where:

$S$ = diameter or span (in.)
$E$ = modulus of elasticity (ksi)
$I$ = moment of inertia (in.$^4$/in.)

The value of $C_S$ from Eq. 12.13.3.5-1 shall not be less than the values for steel tunnel liner plate as given in Article 12.5.6.4.

**C12.13.3.5**

The liner plate ring should have sufficient rigidity to resist the unbalanced loads of normal construction from grouting, local slough-ins, and miscellaneous concentrated loads.

The minimum construction stiffness required for these loads, $C_S$, can be expressed for convenience by the formula below. It must be recognized, however, that the limiting values given here are only recommended minimums. Actual job conditions may require greater effective stiffness. Final determination of this factor should be based on intimate knowledge of the project and on practical experience.

The construction stiffness, $C_S$, given by Eq. 12.13.3.5-1, considers the moment of inertia of an individual plate.

## 12.14—PRECAST REINFORCED CONCRETE THREE-SIDED STRUCTURES

### 12.14.1—General

The provisions herein shall apply to the design of precast reinforced concrete three-sided structures supported on a concrete footing foundation.

### 12.14.2—Materials

#### 12.14.2.1—Concrete

Concrete shall conform to Article 5.4.2, except that evaluation of $f'_c$ may also be based on cores.

#### 12.14.2.2—Reinforcement

Reinforcement shall meet the requirements of Article 5.4.3, except that for welded wire fabric a yield strength of 65,000 psi may be used. For wire fabric, the spacing of longitudinal wires shall be a maximum of 8.0 in. Circumferential welded wire fabric spacing shall not be greater than 4.0 in. or less than 2.0 in. Prestressing, if used, shall be in accordance with Article 5.9.

### 12.14.3—Concrete Cover for Reinforcement

The minimum concrete cover for reinforcement in precast three-sided structures reinforced with welded wire fabric shall be taken as three times the wire diameter, but not less than 1.0 in., except for the reinforcement in the top of the top slab of structures covered by less than 2.0 ft of fill, in which case the minimum cover shall be taken as 2.0 in.

### 12.14.4—Geometric Properties

Except as noted herein, the shape of the precast three-sided structures may vary in span, rise, wall thickness, haunch dimensions, and curvature. Specific geometric properties shall be specified by the manufacturer. Wall thicknesses shall be a minimum of 8.0 in. for spans under 24.0 ft and 10.0 in. for 24.0 ft and larger spans.

### 12.14.5—Design

#### 12.14.5.1—General

Designs shall conform to applicable sections of these Specifications, except as provided otherwise herein. Analysis shall be based on a pinned connection at the footing and shall take into account anticipated footing movement.

### C12.14.1

Units may be manufactured using conventional structural concrete and forms (formed) or machine made using dry concrete and vibrating forms.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 12.14.5.2—Distribution of Concentrated Load Effects in Top Slab and Sides

Distribution of wheel loads and concentrated loads for the top slab and sides of three-sided structures shall be taken as specified in Article 12.11.2.1.

### 12.14.5.3—Distribution of Concentrated Loads in Skewed Culverts

Wheel loads on skewed culverts shall be distributed using the same provisions as given for culverts with main reinforcement parallel to traffic. For culvert elements with skews greater than 15 degrees, the effect of the skew shall be considered in analysis.

### 12.14.5.4—Shear Transfer in Transverse Joints between Culvert Sections

The provisions of Article 4.6.2.10.4 shall apply.

In addition, except as provided herein, a means of shear transfer between adjacent units shall be provided in the top slab of structures having flat tops under less than 2.0 ft of fill and subjected to vehicular live loads. Shear transfer between adjacent units may be considered adequate where the thickness of the top slab is equal to or greater than:

- For prestressed slabs:

$$\frac{S}{28} \qquad (12.14.5.4\text{-}1)$$

- For non-prestressed slabs:

$$\frac{(S+10)}{30} \qquad (12.14.5.4\text{-}2)$$

where:

$S$ = clear span (ft) measured parallel to the joint with the adjacent section

### 12.14.5.5—Span Length

When monolithic haunches inclined at 45 degrees are taken into account, negative reinforcement in walls and slabs may be proportioned on the basis of flexural moment at the intersection of the haunch and uniform depth member.

### C12.14.5.4

Flat top structures with less than 2.0 ft of fill and with top slabs that are thinner than specified in this Article may experience differential deflection of adjacent units which can cause pavement cracking if a means of shear transfer is not utilized.

The specified minimum slab thickness and span-to-slab thickness ratios reflect years of experience in the design and construction of flat top three-sided structures and are influenced by Table 9.5(a) of ACI 318-08 and Table 8.9.2 of the *AASHTO Standard Specifications for Highway Bridges*, 17th Ed. Past performance of flat top three-sided structures designed in accordance with these provisions provides additional support for this exception.

For skewed sections, design is based on the span measured parallel to the joint with the adjacent section. This is a longer span than measured perpendicular to the end walls. However, designing for a longer span provides additional reinforcement to address the non-uniform stresses introduced by the skewed geometry which are not explicitly considered for modest skew angles.

Arch-top structures, because of their geometry and interaction with the surrounding soil, do not exhibit significant differential deflections that could cause pavement cracking for structures with less than 2.0 ft of fill. Thus, the requirements of this Article do not apply to arch-top structures.

The minimum thickness provision of this Section pertains only to addressing the need for shear transfer between adjacent three-sided sections. All other provisions of this Specification must be met.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

#### 12.14.5.6—Resistance Factors

The provisions of Articles 12.5.5 and 1.3.1 shall apply as appropriate.

#### 12.14.5.7—Crack Control

The provisions of Article 5.6.4 for buried structures shall apply.

#### 12.14.5.8—Minimum Reinforcement

The provisions of Article 5.9.5.5 shall not be taken to apply to precast three-sided structures.

The primary flexural reinforcement in the direction of the span shall provide a ratio of reinforcement area to gross concrete area at least equal to 0.002. Such minimum reinforcement shall be provided at all cross-sections subject to flexural tension, at the inside face of walls, and in each direction at the top of slabs of three-sided sections with less than 2.0 ft of fill.

#### 12.14.5.9—Deflection Control at the Service Limit State

The deflection limits for concrete structures specified in Article 2.5.2.6.2 shall be taken as mandatory and pedestrian usage as limited to urban areas.

#### 12.14.5.10—Footing Design

Design shall include consideration of differential horizontal and vertical movements and footing rotations. Footing design shall conform to the applicable Articles in Sections 5 and 10.

#### 12.14.5.11—Structural Backfill

Specification of backfill requirements shall be consistent with the design assumptions used. The contract documents should require that a minimum backfill compaction of 90 percent Standard Proctor Density be achieved to prevent roadway settlement adjacent to the structure. A higher backfill compaction density may be required on structures utilizing a soil–structure interaction system.

#### 12.14.5.12—Scour Protection and Waterway Considerations

The provisions of Article 2.6 shall apply as appropriate.

## 12.15—FIBERGLASS PIPE

### 12.15.1—General

The provisions of this Article shall apply to the structural design of solid wall buried fiberglass pipe.

### C12.15.1

The provisions of this Article are based on Chapter 5 of AWWA's *Manual of Water Supply Practices—M45*,

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

"Fiberglass Pipe Design." The internal pressure design requirements of M45 have been omitted here as culverts are typically designed for gravity flow.

Specific design requirements rely on the provisions for thermoplastic pipe as modified in this Article. Not all thermoplastic pipe design requirements are applicable to fiberglass pipe design.

**12.15.2—Section Properties**

Section properties for service and strength limit state calculations for solid wall fiberglass pipe shall be determined from the manufacturer's published nominal wall thickness, and from the nominal diameter requirements of ASTM D3262, Tables 2 and 3. Fiber-reinforced wall thickness shall be determined in accordance with ASTM D3567.

**12.15.3—Mechanical Requirements**

**C12.15.3**

Solid wall fiberglass pipe mechanical properties shall be determined as specified in this Article.

Because of the composite nature of fiberglass pipe, variety of manufacturing processes, and variables such as the amount, type, and orientation of fiber reinforcement, mechanical properties used in design must be actual properties from test results and measurements of the pipe in accordance with ASTM D3262 and ASTM D3567, as required in this Article.

**12.15.3.1—Circumferential Flexural Modulus**

**C12.15.3.1**

The design value for circumferential flexural modulus of the pipe, $E_{cf}$, shall be calculated from pipe stiffness test results, conducted in accordance with ASTM D3262, using the pipe's fiber-reinforced wall thickness determined in accordance with Article 12.15.2.

Appendix 2 of ASTM D2412 includes discussion on determining the circumferential flexural modulus from pipe stiffness test results.

**12.15.3.2—Long-Term Ring-Bending Strain**

**C12.15.3.2**

The design value for long-term ring-bending strain, $S_b$, shall be determined from tests in accordance with ASTM D5365 using a water test solution with a pH between 5 and 9. Test data shall be statistically extrapolated to 75 years. Alternatively, the results from tests in accordance with ASTM D3681 may be used when tested in a solution of 1N $H_2SO_4$ with the results extrapolated to 75 years.

As fiberglass pipe was originally designed for sanitary sewer applications, testing in acid is common and results are generally available from manufacturers. Testing in acid gives conservative results over water, and, if the results are already available, eliminates the need for the manufacturer to perform additional testing in water.

**12.15.4—Total Allowable Deflection**

**C12.15.4**

The total allowable deflection, $\Delta_A$ (in.), shall be 5.0 percent of the inside diameter of the pipe or a lower deflection as specified by the Engineer. The total allowable deflection and the upper deflection limit where remediation or replacement is required shall be prominently displayed in the construction documents.

Higher stiffness fiberglass pipe is easily produced for specific installations by increasing the quantity of glass fiber reinforcement or the wall thickness, or both. The allowable deflection for higher stiffness pipes may need to be reduced.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

## 12.15.5—Service Limit States

### 12.15.5.1—General

Similar to other types of buried flexible pipe, fiberglass pipe shall be installed in a manner that will ensure that external loads will not cause a long-term decrease in the vertical diameter of the pipe exceeding the total allowable deflection in Article 12.15.4.

### 12.15.5.2—Deflection Requirement

The deflection requirements for thermoplastic pipe in Article 12.12.2.2 shall apply with the total allowable deflection, $\Delta_A$, as defined in Article 12.15.4, and total deflection, $\Delta_t$, determined as:

$$\Delta_t = \frac{D_o K_B \left( D_L P_{sp} + C_L P_L \right)}{1{,}000 \left( E_{cf} I_p / R^3 + 0.061 M_s \right)} \qquad (12.15.5.2\text{-}1)$$

where:

$\Delta_t$ = total deflection of pipe, expressed as a reduction of the vertical diameter and taken as positive for a reduction in the vertical diameter (in.)
$D_o$ = outside diameter of pipe, as specified in Article 12.15.2 (in.)
$K_B$ = bedding coefficient, as specified in Article 12.12.2.2
$D_L$ = deflection lag factor, as specified in Article 12.12.2.2
$P_{sp}$ = soil prism pressure ($EV$), evaluated at the top of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi)
$C_L$ = live load distribution coefficient, as specified in Article 12.12.3.5
$P_L$ = service live load on pipe, as specified in Article 12.6.1 (psi)
$E_{cf}$ = circumferential flexural modulus as defined in Article 12.15.3.1 (ksi)
$I_p$ = moment of inertia of the fiber-reinforced pipe wall per unit length ($in.^4/in.$)
$R$ = radius of pipe to centroid of pipe wall (in.)
$M_s$ = constrained soil modulus as specified in Table 12.12.3.5-1 (ksi)

**C12.15.5.2**

This Article is similar to Article 12.12.2.2 for thermoplastic pipe; however, the critical loading for fiberglass pipe occurs due to flexural tension at the invert. Axial compressive thrust in fiberglass pipe is not significant due to the solid wall and high modulus and is therefore ignored. However, the solid wall and high modulus do increase the service load on the pipe to the total soil prism load. Thus, Article 12.12.2.2 is adapted to fiberglass pipe by eliminating the thrust component of deflection and calculating the load as the soil prism pressure at the crown of the pipe.

## 12.15.6—Safety Against Structural Failure

### 12.15.6.1—General

Buried fiberglass culverts shall be investigated at the strength limit states for flexure (ring-bending), global buckling, and flexibility limit.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**12.15.6.2—Flexure**

Factored long-term strain due to flexure shall satisfy:

$$\varepsilon_f \le \phi_f S_b \qquad (12.15.6.2\text{-}1)$$

where:

$\varepsilon_f$ = factored long-term strain due to flexure, determined in accordance with Eq. 12.12.3.10.2b-3 as modified below (in./in.)
$\phi_f$ = resistance factor for flexure, as defined in Table 12.5.5-1
$S_b$ = long-term ring-bending strain, as defined in Article 12.15.3.2

The variable $\Delta_f$ in Eq. 12.12.3.10.2b-3 shall be set to $\Delta_A$, as specified in Article 12.15.4.

**12.15.6.3—Global Buckling**

Loads to be considered for global buckling of fiberglass culverts shall include hydrostatic groundwater, soil pressure, and live loads. Factored buckling strain demand shall satisfy:

$$\varepsilon_{fb} \le \phi_{bck}\varepsilon_{bck} \qquad (12.15.6.3\text{-}1)$$

in which:

$$\varepsilon_{fb} = \frac{(\gamma_{WA}\eta_{EV}H_w\gamma_w/144 + \gamma_{EV}\eta_{EV}P_{sp}R_w + \gamma_{LL}\eta_{LL}C_LP_L)R}{1{,}000E_{cf}A_g} \qquad (12.15.6.3\text{-}2)$$

in which:

$$R_w = 1 - 0.33\frac{H_w}{H} \text{ for } 0 \le H_w \le H \qquad (12.15.6.3\text{-}3)$$

where:

$\varepsilon_{fb}$ = factored buckling strain demand (in./in.)
$\phi_{bck}$ = resistance factor for global buckling as defined in Table 12.5.5-1
$\varepsilon_{bck}$ = nominal strain capacity for general buckling, determined in accordance with Eq. 12.12.3.10.1e-2 as modified below (in./in.)
$\gamma_{WA}$ = load factor for hydrostatic pressure
$\eta_{EV}$ = load modifier for vertical earth pressure on buried structures, from Article 1.3.2 applied in accordance with Article 12.5.4
$H_w$ = height of water over top of pipe (ft)
$\gamma_w$ = unit weight of water (lb/ft$^3$)
$\gamma_{EV}$ = load factor for vertical earth pressure

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$P_{sp}$ = soil prism pressure (EV), evaluated at the crown of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi)
$R_w$ = water buoyancy factor
$\gamma_{LL}$ = load factor for live load
$\eta_{LL}$ = load modifier for live load on buried structures, from Article 1.3.2 applied in accordance with Article 12.5.4
$C_L$ = live load distribution coefficient, as specified in Article 12.12.3.5
$P_L$ = service live load on pipe, as specified in Article 12.6.1 (psi)
$R$ = radius of pipe to centroid of pipe wall (in.)
$E_{cf}$ = circumferential flexural modulus, as defined in Article 12.15.3.1 (ksi)
$A_g$ = area of fiber-reinforced wall of the pipe per unit length, determined from reinforced wall thickness measurements ($in.^2/in.$)
$H$ = height of fill above top of pipe (ft)

The variables $E_p$ and $A_{eff}$ in Eq. 12.12.3.10.1e-2 shall be replaced with $E_{cf}$ and $A_g$, respectively.

#### 12.15.6.4—Flexibility Limit

The flexibility factor for fiberglass pipe shall be determined in accordance with Article 12.12.3.6, but with the variable $E$ in Eq. 12.12.3.6-1 set to $E_{cf}$, as defined in Article 12.15.3.1. The flexibility factor shall be limited as specified in Article 12.5.6.3.

### 12.15.7—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 30, "Thermoplastic Culverts," of the *AASHTO LRFD Bridge Construction Specifications.*

| 20 × 9 ½ in. Corrugations | | |
| Coated Thickness (in.) | Bolt Diameter (in.) | 12 Bolts/Corrugation (lb/ft of seam) |
| 0.280 | 7/8 | 197,000[a] |
| 0.319 | 7/8 | 218,000[a] |
| 0.380 | 7/8 | 267,000[a] |

[a] The number of bolts per corrugation includes the bolts in the corrugation crest, tangent, and valley; the number of bolts within one pitch. The ultimate seam strengths listed are based on tests of staggered seams in assemblies fabricated from panels with a nominal width of 40.0 in. and include the contribution of additional bolts at the stagger. The ultimate seam strengths listed are only applicable for panels with a nominal width of 40.0 in. and staggered seams.

[b] Seam strengths determined based on tests on specimens with 3 corrugation widths.

Note: The listed ultimate seam strengths are only applicable for panels with a nominal width of 30.0 in. and with staggered seams. The number of bolts per corrugation includes bolts within one pitch: those in the corrugation crest and in the corrugation valley. The ultimate seam strengths listed are based on tests of staggered seams in assemblies fabricated from panels with a nominal width of 30.0 in. and include the contribution of additional bolts at the stagger.

# SECTION 13

# RAILINGS

## 13.1—SCOPE

This Section applies to railings for new bridges and for rehabilitated bridges to the extent that railing replacement is determined to be appropriate.

This Section provides six bridge railing test levels and their associated crash test requirements. Guidance for determining the level to meet the warrants for the more common types of bridge sites and guidance for structural and geometric design of railings are provided.

A process for the design of crash test specimens to determine their crashworthiness is described in Appendix A13. This methodology is based on an application of the yield line theory. For use beyond the design of test specimens with expected failure modes similar to those shown in Figures CA13.3.1-1 and CA13.3.1-2, a rigorous yield line solution or a finite element solution should be developed. The procedures of Appendix A13 are not applicable to traffic railings mounted on rigid structures, such as retaining walls or spread footings, when the cracking pattern is expected to extend to the supporting components.

## C13.1

All bridge traffic barrier systems will be referred to as railings herein.

The bridge railing performance need not be identical over the whole highway network. New railing designs should match site needs leading to a multiple test level concept, as described in NCHRP Report 350 or AASHTO's *Manual for Assessing Safety Hardware* (MASH).

All highway safety hardware accepted prior to the adoption of MASH, using criteria contained in NCHRP Report 350, may remain in place and may continue to be manufactured and installed. Highway safety hardware accepted using NCHRP Report 350 criteria is not required to be retested using MASH criteria. New highway safety hardware not previously evaluated must utilize MASH for testing and evaluation.

With the finite resources available to bridge owners, it is not reasonable to expect all existing rails to be updated any more than to expect every existing building to be immediately updated with the passing of a new building code. Many existing bridge rails have proven functional and need only be replaced when removed for bridge widenings.

## 13.2—DEFINITIONS

*Agency*—A responsible business or service authorized to act on behalf of others, e.g., a governmental department, consulting engineering firm, or owner of the facility or feature.

*Barrier Curb*—A platform or block used to separate a raised sidewalk for pedestrians, bicycles, or both above the roadway level; see Figure 13.7.1.1-1.

*Bicycle Railing*—A railing or fencing system, as illustrated in Figure 13.9.3-1, that provides a physical guide for bicyclists crossing bridges to minimize the likelihood of a bicyclist falling over the system.

*Bridge Approach Railing*—A roadside guardrail system preceding the structure and attached to the bridge rail system that is intended to prevent a vehicle from impacting the end of the bridge railing or parapet.

*Combination Railing*—A bicycle or pedestrian railing system, as illustrated in Figures 13.8.2-1 and 13.9.3-1, added to a crashworthy bridge vehicular railing or barrier system.

*Concrete Barrier*—A railing system of reinforced concrete having a traffic face that usually but not always adopts some form of a safety shape.

*Concrete Parapet*—A railing system of reinforced concrete, usually considered an adequately reinforced concrete wall.

*Crash Testing of Bridge Railings*—Conducting a series of full-scale impact tests of a bridge railing in accordance with the recommended guidelines in NCHRP Report 350 or AASHTO's *Manual for Assessing Safety Hardware* in order to evaluate the railing's strength and safety performance.

*Crashworthy*—A system that has been successfully crash-tested to a currently acceptable crash test matrix and test level or one that can be geometrically and structurally evaluated as equal to a crash-tested system.

All rights reserved. Duplication is a violation of applicable law.

*Design Force*—An equivalent static force that represents the dynamic force imparted to a railing system by a specified vehicle impacting a railing at a designated speed and angle.

*Encroachment*—An intrusion into prescribed, restrictive, or limited areas of a highway system, such as crossing a traffic lane or impacting a barrier system. Also, the occupancy of highway right-of-way by nonhighway structures or objects of any kind or character.

*End Zone*—The area adjacent to any open joint in a concrete railing system that requires added reinforcement.

*Expressway*—A controlled access arterial highway that may or may not be divided or have grade separations at intersections.

*Face of the Curb*—The vertical or sloping surface on the roadway side of the curb.

*Freeway*—A controlled access divided arterial highway with grade separations at intersections.

*Longitudinal Loads*—Horizontal design forces that are applied parallel to the railing or barrier system and that result from friction on the transverse loads.

*Multiple-Use Railing*—Railing that may be used either with or without a raised sidewalk.

*Owner*—An authority or governmental department representing investors and/or taxpayers that is responsible for all the safety design features and functions of a bridge.

*Pedestrian Railing*—A railing or fencing system, as illustrated in Figure 13.8.2-1, providing physical guidance for pedestrians across a bridge so as to minimize the likelihood of a pedestrian falling over the system.

*Post*—A vertical or sloping support member of a rail system that anchors a railing element to the deck.

*Rail Element*—Any component that makes up a railing system. It usually pertains to a longitudinal member of the railing.

*Severity*—A characterization of the degree of an event. It is usually associated with characterizing accidents as fatal, injury, or property damage only so that a dollar value can be assessed for economic study. It may also pertain to indexing the intensity of an accident so that a railing system can be assessed as a preventive or safety measure.

*Speeds—Low/High*—Vehicle velocities in mph. Low speeds are usually associated with city or rural travel where posted speeds do not exceed 45 mph. High speeds are usually associated with expressways or freeways where posted speeds are in excess of 45 mph.

*Traffic Railing*—Synonymous with vehicular railing; used as a bridge- or structure-mounted railing, rather than a guardrail or median barrier as in other publications.

*Transverse Loads*—Horizontal design forces that are applied perpendicular to a railing or barrier system.

*Vehicle Rollover*—A term used to describe an accident in which a vehicle rotates at least 90° about its longitudinal axis after contacting a railing. This term is used if the vehicle rolls over as a result of contacting a barrier and not another vehicle.

*Warrants*—A document that provides guidance to the Designer in evaluating the potential safety and operational benefits of traffic control devices or features. Warrants are not absolute requirements; rather, they are a means of conveying concern over a potential traffic hazard.

## 13.3—NOTATION

$A_f$ = area of post compression flange (in.$^2$) (A13.4.3.2)
$B$ = out-to-out wheel spacing on an axle (ft); distance between centroids of tensile and compressive stress resultants in post (in.) (A13.2) (A13.4.3.2)
$b$ = length of deck resisting post strength or shear load (ft) (A13.4.3.1)
$C$ = vertical post capacity or compression flange resistance of post in bending (kip-ft) (CA13.4.3.2)
$d_b$ = distance from the outer edge of the base plate to the innermost row of bolts (in.) (A13.4.3.1)
$E$ = distance from edge of slab to centroid of compressive stress resultant in post (in.) (A13.4.3.2)
$F_L$ = longitudinal friction force along rail = 0.33 $F_t$ (kips) (A13.2)
$F_t$ = transverse vehicle impact force distributed over a length $L_t$ at a height $H_e$ above bridge deck (kips) (A13.2)
$F_v$ = vertical force of vehicle laying on top of rail (kips) (A13.2)
$F_y$ = yield strength of post-compression flange (ksi) (A13.4.3.2)
$f_c'$ = 28-day compressive strength of concrete (ksi) (A13.4.3.2)
$G$ = height of vehicle center of gravity above bridge deck (in.) (A13.2)
$H$ = height of wall (ft) (A13.3.1)
$H_R$ = height of rail (ft) (A13.3.3)
$H_w$ = height of wall (ft) (A13.3.3)
$h$ = depth of slab (in.) (A13.4.3.2)
$L$ = post spacing of single span (ft) (A13.3.2)
$L_c$ = critical length of wall failure (ft) (A13.3.1)
$L_L$ = longitudinal length of distribution of friction force $F_L$, $L_L = L_t$ (ft) (A13.2)
$L_t$ = longitudinal length of distribution of impact force $F_t$ along the railing located a height of the $H_e$ above the deck (ft) (A13.2)
$L_v$ = longitudinal distribution of vertical force $F_v$ on top of railing (ft) (A13.2)
$\ell$ = length of vehicle impact load on railing or barrier taken as $L_t$, $L_v$, or $L_L$, as appropriate (ft) (A13.3.1)
$M_b$ = ultimate moment capacity of beam at top of wall (kip-ft) (A13.3.1)
$M_c$ = ultimate flexural resistance of wall about horizontal axis (kip-ft/ft) (A13.3.1)
$M_d$ = deck overhang moment (kip-ft/ft) (A13.4.3.1)
$M_p$ = plastic or yield line resistance of rail (kip-ft) (A13.3.2)
$M_{post}$ = plastic moment resistance of a single post (kip-ft) (A13.3.2)
$M_w$ = ultimate flexural resistance of wall about vertical axis (kip-ft) (A13.3.1)
$P_p$ = shear force on a single post which corresponds to $M_{post}$ and is located $\overline{Y}$ above the deck (kips) (A13.3.2)
$R$ = total ultimate resistance, i.e., nominal resistance, of the railing (kips) (A13.3.2)
$R_R$ = ultimate capacity of rail over one span (kips) (A13.3.3)
$R_R'$ = ultimate transverse resistance of rail over two spans (kips) (A13.3.3)
$R_w$ = total transverse resistance of the railing (kips); ultimate capacity of wall as specified in Article A13.3.1 (kips) (A13.3.1) (A13.3.3)
$R_w'$ = capacity of wall, reduced to resist post load (kips) (A13.3.3)
$\overline{R}$ = sum of horizontal components of rail strengths (kips) (A13.2)
$T$ = tensile force per unit of deck length (kip/ft) (A13.4.2)
$v_c$ = nominal shear resistance provided by tensile stresses in the concrete (ksi) (A13.4.3.2)
$V_n$ = nominal shear resistance of the section considered (kips) (A13.4.3.2)
$V_r$ = factored shear resistance (kips) (A13.4.3.2)
$V_u$ = factored shear force at section (kips) (A13.4.3.2)
$W$ = weight of vehicle corresponding to the required test level, from Table 13.7.2-1 (kips) (13.7.2)
$W_b$ = width of base plate (in.) (A13.4.3.1)
$X$ = length of overhang from face of support to exterior girder or web (ft) (A13.4.3.1)
$\overline{Y}$ = height of $\overline{R}$ above bridge deck (in.) (A13.2)
$\beta_c$ = ratio of the long side to the short side of the concentrated load or reaction area (A13.4.3.2)
$\phi$ = resistance factor = 1.0 (A13.4.3.2)

## 13.4—GENERAL

The owner shall develop the warrants for the bridge site. A bridge railing should be chosen to satisfy the concerns of the warrants as completely as possible and practical.

Railings shall be provided along the edges of structures for protection of traffic and pedestrians. Other applications may be warranted on bridge-length culverts.

A pedestrian walkway may be separated from an adjacent roadway by a barrier curb, traffic railing, or combination railing, as indicated in Figure 13.4-1. On high-speed urban expressways where a pedestrian walkway is provided, the walkway area shall be separated from the adjacent roadway by a traffic railing or combination railing.

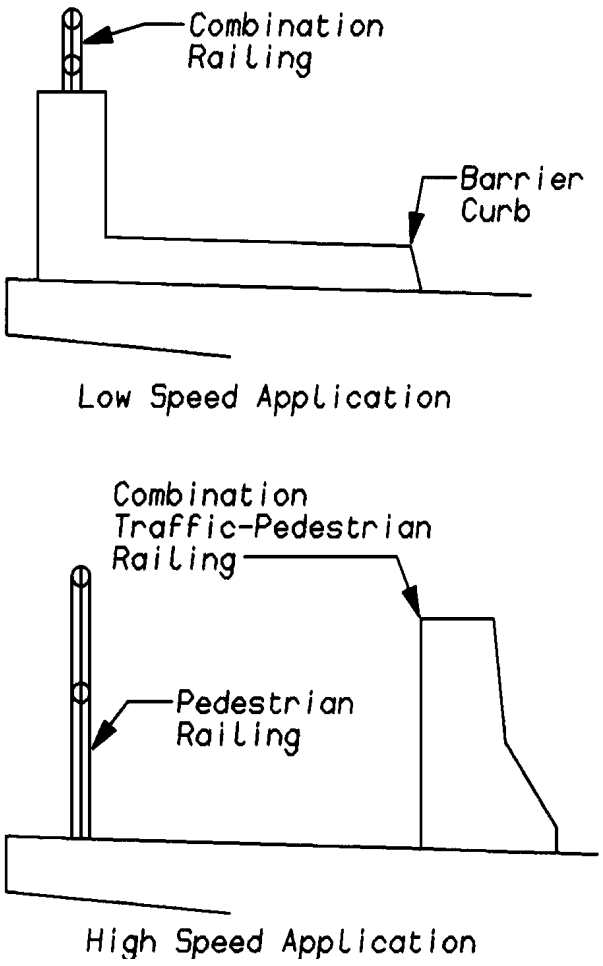

**Figure 13.4-1—Pedestrian Walkway**

New bridge railings and the attachment to the deck overhang shall satisfy crash testing requirements to confirm that they meet the structural and geometric requirements of a specified railing test level using the test criteria specified in Article 13.7.2.

## C13.4

Additional guidance applicable to bridge-length culverts may be found in the AASHTO *Roadside Design Guide*.

The following guidelines indicate the application of various types of rails:

- Traffic railing is used when a bridge is for the exclusive use of highway traffic;
- A combination barrier in conjunction with a raised curb and sidewalk is used only on low-speed highways;
- On high-speed highways, the pedestrian or bicycle path should have both an outboard pedestrian or bicycle railing and an inboard combination railing; and
- Separate pedestrian bridges should be considered where the amount of pedestrian traffic or other risk factors so indicate.

For the purpose of this Article, low speed may be taken as speeds up to and including 45 mph. High speed may be taken as speeds in excess of 45 mph.

The walkway faces of combination railings separating walkways from adjacent roadways serve as pedestrian or bicycle railings. When the height of such railings above the walkway surface is less than the minimum height required for pedestrian or bicycle railings, as appropriate, the Designer may consider providing additional components, such as metal rails, on top of the combination railing. The additional components need to be designed for the appropriate pedestrian or bicycle railing design forces.

Warning devices for pedestrians are beyond the scope of these Specifications, but they should be considered.

Procedures for testing railings are given in MASH.

All rights reserved. Duplication is a violation of applicable law.

## 13.5—MATERIALS

The requirements of Sections 5, 6, 7, and 8 shall apply to the materials employed in a railing system, unless otherwise modified herein.

**C13.5**

Factors to be considered in choosing the material for use in any railing system include ultimate strength, durability, ductility, maintenance, ease of replacement, and long-term behavior.

## 13.6—LIMIT STATES AND RESISTANCE FACTORS

### 13.6.1—Strength Limit State

The strength limit states shall apply using the applicable load combinations in Table 3.4.1-1 and the loads specified herein. The resistance factors for post and railing components shall be as specified in Articles 5.5.4, 6.5.4, 7.5.4, and 8.5.2.

Design loads for pedestrian railings shall be as specified in Article 13.8.2. Design loads for bicycle railings shall be as specified in Article 13.9.3. Pedestrian or bicycle loadings shall be applied to combination railings as specified in Article 13.10.3. Deck overhangs shall be designed for applicable strength load combinations specified in Table 3.4.1-1.

### 13.6.2—Extreme Event Limit State

The forces to be transmitted from the bridge railing to the bridge deck may be determined from an ultimate strength analysis of the railing system using the loads given in Appendix A13. Those forces shall be considered to be the factored loads at the extreme event limit state.

## 13.7—TRAFFIC RAILINGS

### 13.7.1—Railing System

#### 13.7.1.1—General

**C13.7.1.1**

Variations in traffic volume, speed, vehicle mix, roadway alignment, activities, and conditions beneath a structure, and other factors combine to produce a vast variation in traffic railing performance requirements.

The primary purpose of traffic railings shall be to contain and redirect vehicles using the structure. All new vehicle traffic barrier systems, traffic railings, and combination railings shall be shown to be structurally and geometrically crashworthy.

Consideration should be given to:

- Protection of the occupants of a vehicle in collision with the railing,
- Protection of other vehicles near the collision,
- Protection of persons and property on roadways and other areas underneath the structure,
- Possible future rail upgrading,
- Railing cost-effectiveness, and
- Appearance and freedom of view from passing vehicles.

A combination railing, conforming to the dimensions given in Figures 13.8.2-1 and 13.9.3-1, and crash tested

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

with a sidewalk may be considered acceptable for use with sidewalks having widths 3.5 ft or greater and curb heights up to the height used in the crash test installation.

A railing designed for multiple use shall be shown to be crashworthy with or without the sidewalk. Use of the combination vehicle–pedestrian railing shown in Figure 13.7.1.1-1 shall be restricted to roads designated for 45 mph or less and need to be tested to Test Level 1 or 2.

Because of more recent tests on sidewalks, an 8.0-in. maximum height for sidewalk curbs has generally been accepted.

AASHTO's *A Policy on Geometric Design of Highways and Streets* recommends that a barrier curb be used only for speeds of 45 mph or less. For speeds of 50 mph or greater, pedestrians should be protected by a separation traffic barrier.

A railing intended for use only on a sidewalk need not be tested without the sidewalk.

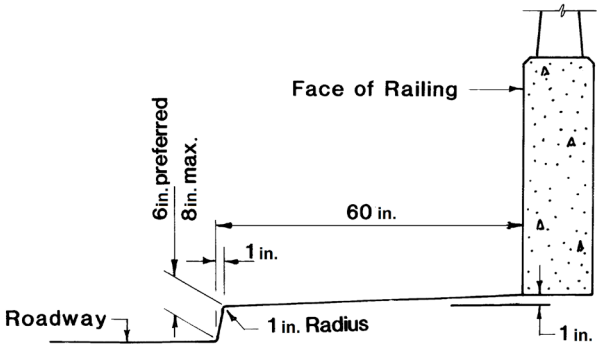

**Figure 13.7.1.1-1—Typical Raised Sidewalk**

### 13.7.1.2—Approach Railings

An approach guardrail system should be provided at the beginning of all bridge railings in high-speed rural areas.

A bridge approach railing system should include a transition from the guardrail system to the rigid bridge railing system that is capable of providing lateral resistance to an errant vehicle. The approach guardrail system shall have a crashworthy end terminal at its nosing.

### C13.7.1.2

In urban areas or where city streets and/or sidewalks prevent installation of approach guardrail transitions or crashworthy terminals, consideration should be given to:

- Extending the bridge rail or guard rail in a manner that prevents encroachment of a vehicle onto any highway system below the bridge,
- Providing a barrier curb,
- Restricting speed,
- Adding signing of intersections, and
- Providing recovery areas.

A bridge end drainage facility should be an integral part of the barrier transition design.

### 13.7.1.3—End Treatment

In high-speed rural areas, the approach end of a parapet or railing shall have a crashworthy configuration or be shielded by a crashworthy traffic barrier.

### C13.7.1.3

If the approach railing is connected to a side-of-road railing system, it can be continuous with the bridge approach system, and only a transition from a flexible to a rigid railing system is required.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 13.7.2—Test Level Selection Criteria

One of the following test levels should be specified:

- TL-1—Test Level One—taken to be generally acceptable for work zones with low posted speeds and very low-volume, low-speed local streets;
- TL-2—Test Level Two—taken to be generally acceptable for work zones and most local and collector roads with favorable site conditions as well as where a small number of heavy vehicles is expected and posted speeds are reduced;
- TL-3—Test Level Three—taken to be generally acceptable for a wide range of high-speed arterial highways with very low mixtures of heavy vehicles and with favorable site conditions;
- TL-4—Test Level Four—taken to be generally acceptable for the majority of applications on high-speed highways, freeways, expressways, and Interstate highways with a mixture of trucks and heavy vehicles;
- TL-5—Test Level Five—taken to be generally acceptable for the same applications as TL-4 and where large trucks make up a significant portion of the average daily traffic or when unfavorable site conditions justify a higher level of rail resistance; and
- TL-6—Test Level Six—taken to be generally acceptable for applications where tanker-type trucks or similar high center of gravity vehicles are anticipated, particularly along with unfavorable site conditions.

It shall be the responsibility of the user agency to determine which of the test levels is most appropriate for the bridge site.

The testing criteria for the chosen test level shall correspond to vehicle weights and speeds and angles of impact outlined in Table 13.7.2-1.

### C13.7.2

The six test levels mentioned herein are intended to correspond with the six test levels contained in AASHTO's *Manual for Assessing Safety Hardware* and NCHRP Report 350, "Recommended Procedures for the Safety Performance Evaluation of Highway Features." AASHTO's *A Policy on Geometric Design of Highways and Streets* and its *Roadside Design Guide* are referred to as aides in the bridge railing selection process.

The individual tests are designed to evaluate one or more of the principal performance factors of the bridge railing, which include structural adequacy, occupant risk, and postimpact behavior of the test vehicle. In general, the lower test levels are applicable for evaluating and selecting bridge railings to be used on segments of lower service level roadways and certain types of work zones. The higher test levels are applicable for evaluating and selecting bridge railings to be used on higher service level roadways or at locations that demand a special, high-performance bridge railing. In this regard, TL-4 railings are expected to satisfy the majority of interstate design requirements.

TL-5 provides for a van-type tractor–trailer that will satisfy design requirements where TL-4 railings are deemed to be inadequate due to the high number of this type of vehicle anticipated, or due to unfavorable site conditions where rollover or penetration beyond the railing could result in severe consequences.

TL-6 provides for a tanker-type truck that will satisfy design requirements where this type vehicle with a higher center of gravity has shown a history of rollover or penetration, or unfavorable site conditions may indicate the need for this level of rail resistance.

Unfavorable site conditions include but are not limited to reduced radius of curvature, steep downgrades on curvature, variable cross slopes, and adverse weather conditions.

Agencies should develop objective guidelines for use of bridge railings. These guidelines should take into account factors such as traffic conditions, traffic volume and mix, cost and in-service performance, and life-cycle cost of existing railings.

These criteria, including other vehicle characteristics and tolerances, are described in detail in MASH and NCHRP Report 350.

## 13.7.3—Railing Design

### 13.7.3.1—General

A traffic railing should normally provide a smooth, continuous face of rail on the traffic side. Steel posts with rail elements should be set back from the face of the rail. Structural continuity in the rail members and anchorages of ends should be considered.

A railing system and its connection to the deck shall be approved only after they have been shown through crash testing to be satisfactory for the desired test level.

#### *13.7.3.1.1—Application of Previously Tested Systems*

A crashworthy railing system may be used without further analysis and/or testing, provided that the proposed installation does not have features that are absent in the tested configuration and that might detract from the performance of the tested railing system.

### C13.7.3.1

Protrusions or depressions at rail openings may be acceptable, provided that their thickness, depth, or geometry does not prevent the railing from meeting the crash test evaluation criteria.

Test specimens should include a representative length of the overhang to account for the effect of deck flexibility on the distance over which the railing engages the deck.

#### *C13.7.3.1.1*

When a minor detail is changed on or an improvement is made to a railing system that has already been tested and approved, engineering judgment and analysis should be used when determining the need for additional crash testing.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*13.7.3.1.2—New Systems*

New railing systems may be used, provided that acceptable performance is demonstrated through full-scale crash tests.

The crash test specimen for a railing system may be designed to resist the applied loads in accordance with Appendix A13.

Provision shall be made to transfer loads from the railing system to the deck. Railing loads may be taken from Appendix A13.

Unless a lesser thickness can be proven satisfactory during the crash testing procedure, the minimum edge thickness for concrete deck overhangs shall be taken as:

- For concrete deck overhangs supporting a deck-mounted post system: 8.0 in.
- For a side-mounted post system: 12.0 in.
- For concrete deck overhangs supporting concrete parapets or barriers: 8.0 in.

*C13.7.3.1.2*

Preliminary design for bridge decks should comply with Article A13.1.2. A determination of the adequacy of deck reinforcement for the distribution of post anchorage loads to the deck should be made during the rail testing program. If the rail testing program satisfactorily models the bridge deck, damage to the deck edge can be assessed at this time.

In adequately designed bridge deck overhangs, the major crash-related damage presently occurs in short sections of slab areas where the barrier is hit.

**13.7.3.2—Height of Traffic Parapet or Railing**

Traffic railings shall be at least 27.0 in. for TL-3, 32.0 in. for TL-4, 42.0 in. for TL-5, and 90.0 in. in height for TL-6.

The bottom 3.0-in. lip of the safety shape shall not be increased for future overlay considerations.

The minimum height for a concrete parapet with a vertical face shall be 27.0 in. The height of other combined concrete and metal rails shall not be less than 27.0 in. and shall be determined to be satisfactory through crash testing for the desired test level.

The minimum height of a pedestrian or bicycle railing should be measured above the surface of the sidewalk or bikeway.

The minimum geometric requirements for combination railings beyond those required to meet crash test requirements shall be taken as specified in Articles 13.8, 13.9, and 13.10.

**C13.7.3.2**

These heights have been determined as satisfactory through crash tests performed in accordance with NCHRP Report 350 and experience.

For future deck overlays, an encroachment of 2.0 in., leaving a 1.0-in. lip, has been satisfactorily tested for safety shapes.

## 13.8—PEDESTRIAN RAILINGS

**13.8.1—Geometry**

The minimum height of a pedestrian railing shall be 42.0 in., measured from the top of the walkway.

A pedestrian railing may be composed of horizontal and/or vertical elements. The clear opening between elements shall be such that a 6.0-in. diameter sphere shall not pass through.

When both horizontal and vertical elements are used, the 6.0-in. clear opening shall apply to the lower 27.0 in. of the railing, and the spacing in the upper portion shall be such that an 8.0-in. diameter sphere shall not pass through. A safety toe rail or curb should be provided. Rails should

**C13.8.1**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

project beyond the face of posts, pickets, or both as shown in Figure A13.1.1-2.

The rail spacing requirements given above should not apply to chain link or metal fabric fence support rails and posts. Mesh size in chain link or metal fabric fence should have openings no larger than 2.0 in.

The size of openings should be capable of retaining an average size beverage container.

### 13.8.2—Design Loads

### C13.8.2

The design live load for pedestrian railings shall be taken as $w$ = 0.050 klf, both transversely and vertically, acting simultaneously. In addition, each longitudinal element will be designed for a concentrated load of 0.20 kips, which shall act simultaneously with the above loads at any point and in any direction at the top of the longitudinal element.

The posts of pedestrian railings shall be designed for a concentrated design live load applied transversely at the center of gravity of the upper longitudinal element or, for railings with a total height greater than 5.0 ft, at a point 5.0 ft above the top surface of the sidewalk. The value of the concentrated design live load for posts, $P_{LL}$, in kips, shall be taken as:

$$P_{LL} = 0.20 + 0.050L \qquad (13.8.2\text{-}1)$$

where:

$L$ = post spacing (ft)

The application of loads shall be as indicated in Figure 13.8.2-1, in which the shapes of rail members are illustrative only. Any material or combination of materials specified in Article 13.5 may be used.

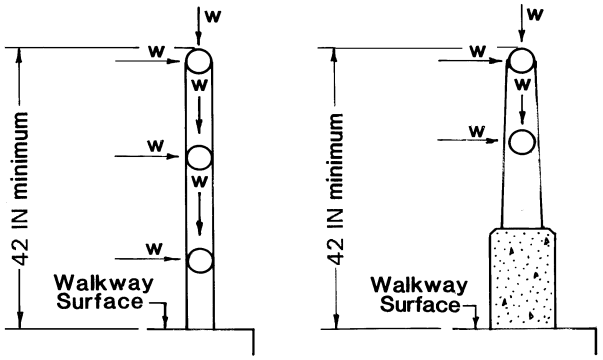

**Figure 13.8.2-1—Pedestrian Railing Loads—To be used on the outer edge of a sidewalk when highway traffic is separated from pedestrian traffic by a traffic railing. Railing shape illustrative only.**

The design wind load for chain link or metal fabric fence shall be taken as 0.015 ksf acting normal to the entire surface. The wind load need not be applied simultaneously with live load.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

## 13.9—BICYCLE RAILINGS

### 13.9.1—General

Bicycle railings shall be used on bridges specifically designed to carry bicycle traffic and on bridges where specific protection of bicyclists is deemed necessary.

### 13.9.2—Geometry

The height of a bicycle railing shall not be less than 42.0 in., measured from the top of the riding surface.

Bicycle railings shall have rail spacing satisfying the respective provisions of Article 13.8.1.

If deemed necessary, rubrails attached to the rail or fence to prevent snagging should be deep enough to protect a wide range of bicycle handlebar heights.

If screening, fencing, or a solid face is utilized, the number of rails may be reduced.

### 13.9.3—Design Live Loads

If the rail height exceeds 54.0 in. above the riding surface, design loads shall be determined by the Designer. The design loads for the lower 54.0 in. of the bicycle railing shall not be less than those specified in Article 13.8.2, except that for railings with total height greater than 54.0 in., the design live load for posts shall be applied at a point 54.0 in. above the riding surface.

The application of loads shall be as indicated in Figure 13.9.3-1. Any material or combination of materials specified in Article 13.5 may be used.

### C13.9.2

Railings, fences, or barriers on either side of a shared use path on a structure, or along bicycle lane, shared use path or signed shared roadway located on a highway bridge should be a minimum of 42.0 in. high. The 42.0-in. minimum height is in accordance with the *AASHTO Guide for the Development of Bicycle Facilities*.

On a bridge or bridge approach where high-speed, high-angle impacts with a railing, fence, or barrier are more likely to occur (such as short-radius curves with restricted sight distance, or at the end of a long descending grade) or in locations with site-specific safety concerns, a railing, fence, or barrier height above the minimum should be considered.

The need for rubrails attached to a rail or fence is controversial among many bicyclists.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

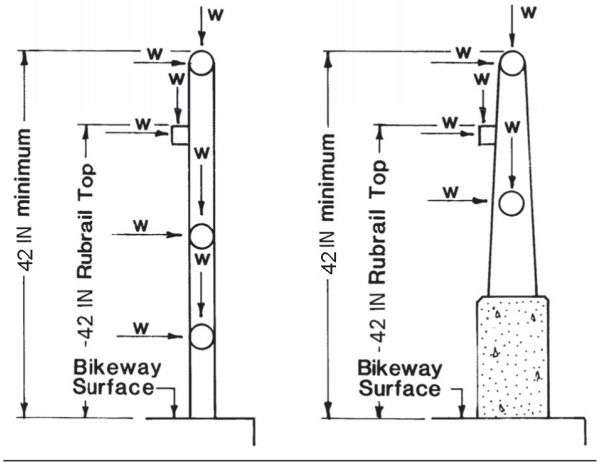

**Figure 13.9.3-1—Bicycle Railing Loads—To be used on the outer edge of a bikeway when highway traffic is separated from bicycle traffic by a traffic railing. Railing shape illustrative only.**

## 13.10—COMBINATION RAILINGS

### 13.10.1—General

The combination railing shall conform to the requirements of either the pedestrian or bicycle railings, as specified in Articles 13.8 and 13.9, whichever is applicable. The traffic railing portion of the combination railing shall conform to Article 13.7.

### 13.10.2—Geometry

The geometric provisions of Articles 13.7, 13.8, and 13.9 shall apply to their respective portions of a combination railing.

### 13.10.3—Design Live Loads

Design loads, specified in Articles 13.8 and 13.9, shall not be applied simultaneously with the vehicular impact loads.

## 13.11—CURBS AND SIDEWALKS

### 13.11.1—General

Horizontal measurements of roadway width shall be taken from the bottom of the face of the curb. A sidewalk curb located on the highway traffic side of a bridge railing shall be considered an integral part of the railing and shall be subject to the crash test requirements specified in Article 13.7.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 13.11.2—Sidewalks

When curb and gutter sections with sidewalks are used on roadway approaches, the curb height for raised sidewalks on the bridge should be no more than 8.0 in. If a barrier curb is required, the curb height should not be less than 6.0 in. If the height of the curb on the bridge differs from that off the bridge, it should be uniformly transitioned over a distance greater than or equal to 20 times the change in height.

### C13.11.2

Raised sidewalks on bridges are not usually provided where the approach roadway is not curbed for pedestrians or the structure is not planned for pedestrian occupancy.

For recommendations on sidewalk width, see Figure 13.7.1.1-1 and AASHTO's *A Policy on Geometric Design of Highways and Streets*.

During stage construction, the same transition considerations will be given to the provision of ramps from the bridge sidewalk to the approach surface.

### 13.11.3—End Treatment of Separation Railing

The end treatment of any traffic railing or barrier shall meet the requirements specified in Articles 13.7.1.2 and 13.7.1.3.

# APPENDIX A13

## A13.1—GEOMETRY AND ANCHORAGES

### A13.1.1—Separation of Rail Elements

For traffic railings, the criteria for maximum clear opening below the bottom rail, $c_b$, the setback distance, $S$, and maximum opening between rails, $c$, shall be as follows:

- The rail contact widths for typical railings may be taken as illustrated in Figure A13.1.1-1;
- The total width of the rail(s) in contact with the vehicle, $\Sigma A$, shall not be less than 25 percent of the height of the railing;
- For post railings, the vertical clear opening, $c$, and the post setback, $S$, shall be within or below the shaded area shown in Figure A13.1.1-2; and
- For post railings, the combination of ($\Sigma A/H$) and the post setback, $S$ shall be within or above the shaded area shown in Figure A13.1.1-3.

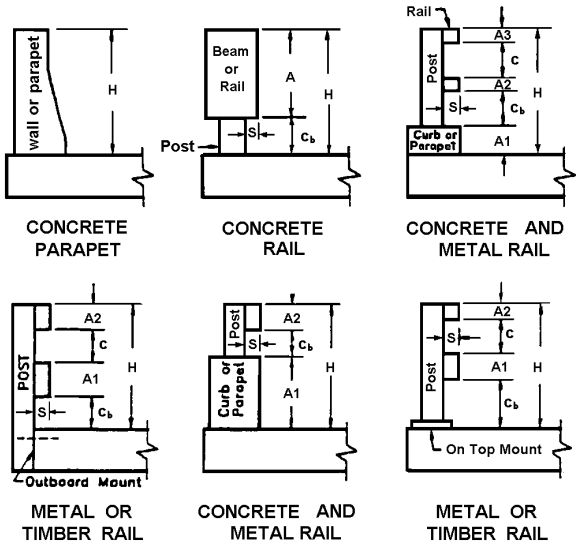

**Figure A13.1.1-1—Typical Traffic Railings**

### CA13.1.1

The post setback shown from face of rail for various post shapes is based on a limited amount of crash test data. The potential for wheel snagging involved with a given design should be evaluated as part of the crash test program.

The post setback, $S$, shown for various shape posts in Figure A13.1.1-2, recognizes the tendency for various shape posts to snag wheels. The implication of the various definitions of setback, $S$, is that all other factors being equal, the space between a rail and the face of a rectangular post will be greater than the distance between a rail and the face of a circular post.

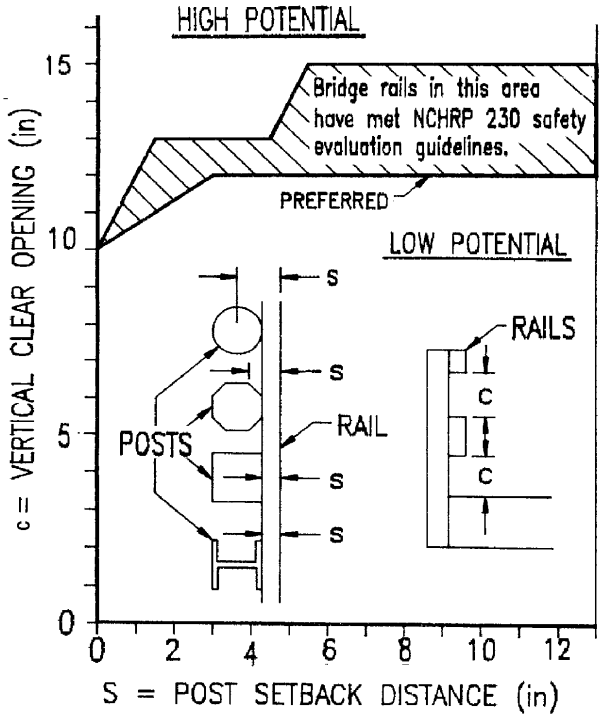

**Figure A13.1.1-2—Potential for Wheel, Bumper, or Hood Impact with Post**

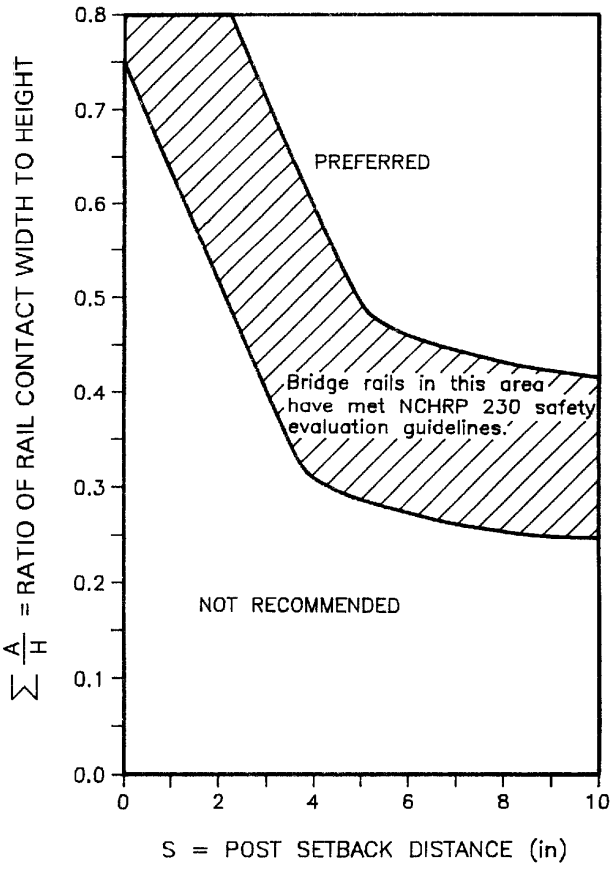

**Figure A13.1.1-3—Post Setback Criteria**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The maximum clear vertical opening between succeeding rails or posts shall be as specified in Articles 13.8, 13.9, and 13.10.

### A13.1.2—Anchorages

The yield strength of anchor bolts for steel railings shall be fully developed by bond, hooks, attachment to embedded plates, or any combination thereof.

Reinforcing steel for concrete barriers shall have embedment length sufficient to develop the yield strength.

### CA13.1.2

Noncorrosive bonding agents for anchor dowels may be cement grout, epoxy, or a magnesium phosphate compound. Sulfur or expansive-type grouts should not be used.

Some bonding agents on the market have corrosive characteristics; these should be avoided.

Development length for reinforcing bars is specified in Section 5.

## A13.2—TRAFFIC RAILING DESIGN FORCES

Unless modified herein, the extreme event limit state and the corresponding load combinations in Table 3.4.1-1 shall apply.

Railing design forces and geometric criteria to be used in developing test specimens for a crash test program should be taken as specified in Table A13.2-1 and illustrated in Figure A13.2-1. The transverse and longitudinal loads given in Table A13.2-1 need not be applied in conjunction with vertical loads.

The effective height of the vehicle rollover force is taken as:

$$H_e = G - \frac{12WB}{2F_t} \qquad \text{(A13.2-1)}$$

where:

$G$ = height of vehicle center of gravity above bridge deck, as specified in Table 13.7.2-1 (in.)
$W$ = weight of vehicle corresponding to the required test level, as specified in Table 13.7.2-1 (kips)
$B$ = out-to-out wheel spacing on an axle, as specified in Table 13.7.2-1 (ft)
$F_t$ = transverse force corresponding to the required test level, as specified in Table A13.2-1 (kips)

Railings shall be proportioned such that:

$$\overline{R} \geq F_t \qquad \text{(A13.2-2)}$$

$$\overline{Y} \geq \frac{H_e}{12} \qquad \text{(A13.2-3)}$$

in which:

$$\overline{R} = \sum R_i \qquad \text{(A13.2-4)}$$

$$\overline{Y} = \frac{\Sigma(R_i Y_i)}{\overline{R}} \qquad \text{(A13.2-5)}$$

### CA13.2

Nomenclature for Eqs. A13.2-1 and A13.2-2 is illustrated in Figure CA13.2-1.

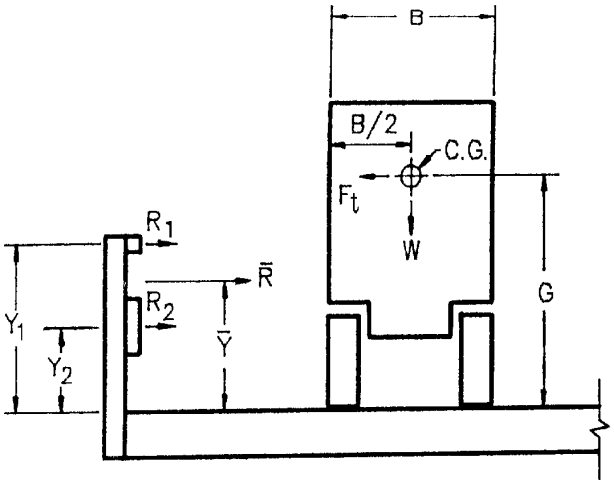

**Figure CA13.2-1—Traffic Railing**

If the total resistance, $\overline{R}$, of a post-and-beam railing system with multiple rail elements is significantly greater than the applied load, $F_t$, then the resistance, $R_i$, for the lower rail element(s) used in calculations may be reduced.

The reduced value of $\overline{R}$ will result in an increase in the computed value of $\overline{Y}$. The reduced notional total rail resistance and its effective height must satisfy Eqs. A13.2-2 and A13.2-3.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

where:

$R_i$ = resistance of the rail (kips)

$Y_i$ = distance from bridge deck to the $i$th rail (ft)

All forces shall be applied to the longitudinal rail elements. The distribution of longitudinal loads to posts shall be consistent with the continuity of rail elements. Distribution of transverse loads shall be consistent with the assumed failure mechanism of the railing system.

Eq. A13.2-1 has been found to give reasonable predictions of effective railing height requirements to prevent rollover.

If the design load located at $H_e$ falls between rail elements, it should be distributed proportionally to rail elements above and below such that $Y \geq H_e$.

As an example of the significance of the data in Table A13.2-1, the length of 4.0 ft for $L_t$ and $L_L$ is the length of significant contact between the vehicle and railing that has been observed in films of crash tests. The length of 3.5 ft for TL-4 is the rear-axle tire diameter of the truck. The length of 8.0 ft for TL-5 and TL-6 is the length of the tractor rear tandem axles: two 3.5-ft diameter tires, plus 1.0 ft between them.

$F_v$, the weight of the vehicle lying on top of the bridge rail, is distributed over the length of the vehicle in contact with the rail, $L_v$.

For concrete railings, Eq. A13.2-1 results in a theoretically-required height, $H$, of 34.0 in. for TL-4. However, a height of 32.0 in., shown in Table A13.2-1, was considered to be acceptable because many railings of that height have been built and appear to be performing acceptably.

The minimum height, $H$, listed for TL-1, TL-2, and TL-3 is based on the minimum railings height used in the past. The minimum effective height, $H_e$, for TL-1 is an estimate based on the limited information available for this test level.

The minimum height, $H$, of 42.0 in., shown in Table A13.2-1, for TL-5 is based on the height used for successfully crash-tested concrete barrier engaging only the tires of the truck. For post-and-beam metal bridge railings, it may be prudent to increase the height by 12.0 in. so as to engage the bed of the truck.

The minimum height, $H$, shown in Table A13.2-1, for TL-6 is the height required to engage the side of the tank as determined by crash test.

**Table A13.2-1—Design Forces for Traffic Railings**

| | Railing Test Levels | | | | | |
|---|---|---|---|---|---|---|
| Design Forces and Designations | TL-1 | TL-2 | TL-3 | TL-4 | TL-5 | TL-6 |
| $F_t$ Transverse (kips) | 13.5 | 27.0 | 54.0 | 54.0 | 124.0 | 175.0 |
| $F_L$ Longitudinal (kips) | 4.5 | 9.0 | 18.0 | 18.0 | 41.0 | 58.0 |
| $F_v$ Vertical (kips) Down | 4.5 | 4.5 | 4.5 | 18.0 | 80.0 | 80.0 |
| $L_t$ and $L_L$ (ft) | 4.0 | 4.0 | 4.0 | 3.5 | 8.0 | 8.0 |
| $L_v$ (ft) | 18.0 | 18.0 | 18.0 | 18.0 | 40.0 | 40.0 |
| $H_e$ (min) (in.) | 18.0 | 20.0 | 24.0 | 32.0 | 42.0 | 56.0 |
| Minimum $H$ Height of Rail (in.) | 27.0 | 27.0 | 27.0 | 32.0 | 42.0 | 90.0 |

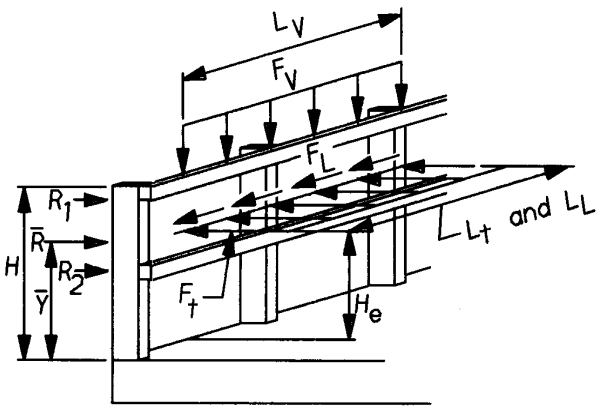

**Figure A13.2-1—Metal Bridge Railing Design Forces, Vertical Location, and Horizontal Distribution Length**

Figure A13.2-1 shows the design forces from Table A13.2-1 applied to a beam and post railing. This is for illustrative purposes only. The forces and distribution lengths shown apply to any type of railing.

## A13.3—DESIGN PROCEDURE FOR RAILING TEST SPECIMENS

### A13.3.1—Concrete Railings

Yield line analysis and strength design for reinforced concrete and prestressed concrete barriers or parapets may be used.

The nominal railing resistance to transverse load, $R_w$, may be determined using a yield line approach as:

- For impacts within a wall segment:

$$R_w = \left(\frac{2}{2L_c - L_t}\right)\left(8M_b + 8M_w + \frac{M_c L_c^2}{H}\right) \quad \text{(A13.3.1-1)}$$

The critical wall length over which the yield line mechanism occurs, $L_c$, shall be taken as:

$$L_c = \frac{L_t}{2} + \sqrt{\left(\frac{L_t}{2}\right)^2 + \frac{8H(M_b + M_w)}{M_c}} \quad \text{(A13.3.1-2)}$$

- For impacts at end of wall or at joint:

$$R_w = \left(\frac{2}{2L_c - L_t}\right)\left(M_b + M_w + \frac{M_c L_c^2}{H}\right) \quad \text{(A13.3.1-3)}$$

$$L_c = \frac{L_t}{2} + \sqrt{\left(\frac{L_t}{2}\right)^2 + H\left(\frac{M_b + M_w}{M_c}\right)} \quad \text{(A13.3.1-4)}$$

where:

$F_t$ = transverse force specified in Table A13.2-1 assumed to be acting at top of a concrete wall (kips)
$H$ = height of wall (ft)
$L_c$ = critical length of yield line failure pattern (ft)

### CA13.3.1

The yield line analysis shown in Figures CA13.3.1-1 and CA13.3.1-2 includes only the ultimate flexural capacity of the concrete component. Stirrups or ties should be provided to resist the shear and/or diagonal tension forces.

The ultimate flexural resistance, $M_s$, of the bridge deck or slab should be determined in recognition that the deck is also resisting a tensile force, caused by the component of the impact forces, $F_t$.

In this analysis, it is assumed that the yield line failure pattern occurs within the parapet only and does not extend into the deck. This means that the deck must have sufficient resistance to force the yield line failure pattern to remain within the parapet. If the failure pattern extends into the deck, the equations for resistance of the parapet are not valid.

The analysis is also based on the assumption that sufficient longitudinal length of parapet exists to result in the yield line failure pattern shown. For short lengths of parapet, a single yield line may form along the juncture of the parapet and deck. Such a failure pattern is permissible, and the resistance of the parapet should be computed using an appropriate analysis.

This analysis is based on the assumption that the negative and positive wall resisting moments are equal and that the negative and positive beam resisting moments are equal.

The measurement of system resistance of a concrete railing is $R_w$, which is compared to the loads in Table A13.2-1 to determine structural adequacy. The flexure resistances, $M_b$, $M_w$, and $M_c$, are related to the system resistance, $R_w$, through the yield line analysis embodied in Eqs. A13.3.1-1 and A13.3.1-2. In the terminology of these Specifications, $R_w$ is the nominal resistance because it is compared to the nominal load given in Table A13.2-1.

Where the width of the concrete railing varies along the height, $M_c$ used in Eqs. A13.3.1-1 through A13.3.1-4 for wall resistance should be taken as the average of its value along the height of the railing.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$L_t$ = longitudinal length of distribution of impact force $F_t$ (ft)
$R_w$ = total transverse resistance of the railing (kips)
$M_b$ = additional flexural resistance of beam in addition to $M_w$, if any, at top of wall (kip-ft)
$M_c$ = flexural resistance of cantilevered walls about an axis parallel to the longitudinal axis of the bridge (kip-ft/ft)
$M_w$ = flexural resistance of the wall about its vertical axis (kip-ft)

For use in the above equations, $M_c$ and $M_w$ should not vary significantly over the height of the wall. For other cases, a rigorous yield line analysis should be used.

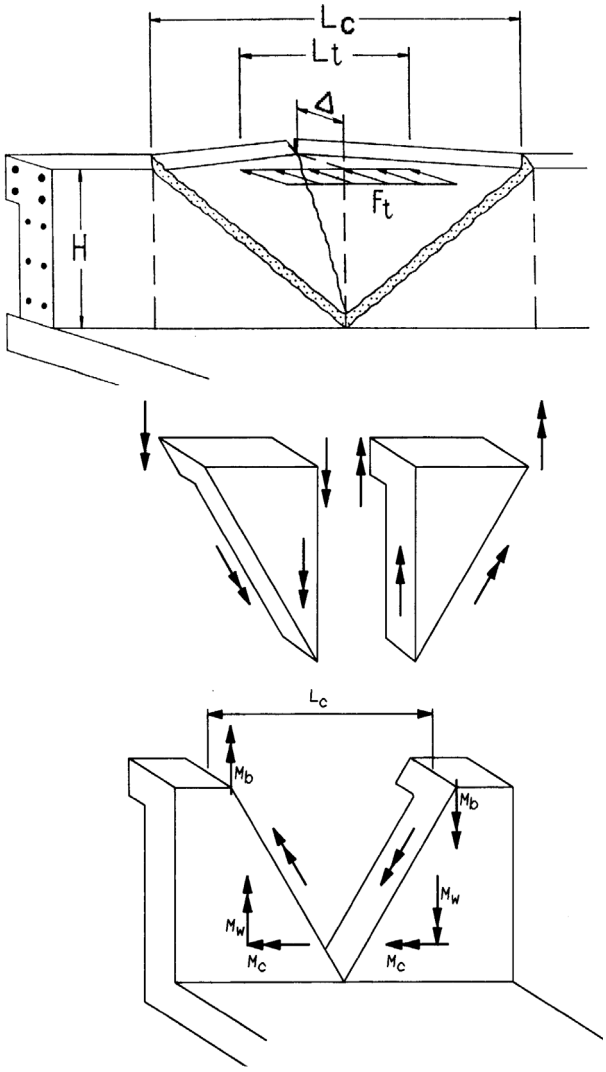

**Figure CA13.3.1-1—Yield Line Analysis of Concrete Parapet Walls for Impact within Wall Segment**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

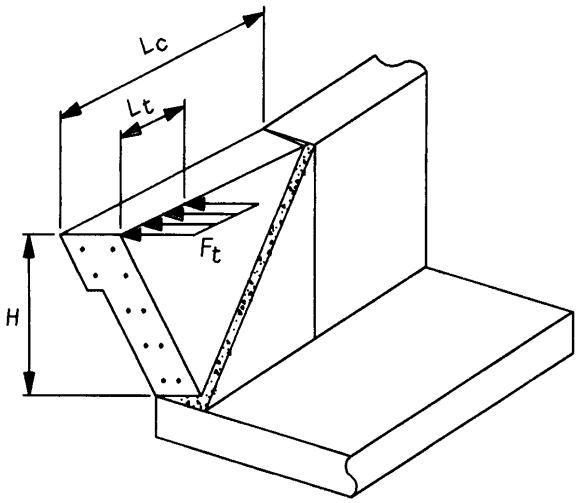

**Figure CA13.3.1-2—Yield Line Analysis of Concrete Parapet Walls for Impact near End of Wall Segment**

### A13.3.2—Post-and-Beam Railings

Inelastic analysis shall be used for design of post-and-beam railings under failure conditions. The critical rail nominal resistance, *R*, when the failure does not involve the end post of a segment, shall be taken as the least value determined from Eqs. A13.3.2-1 and A13.3.2-2 for various numbers of railing spans, *N*.

### CA13.3.2

A basis for applying inelastic analysis is shown in Figure CA13.3.2-1.

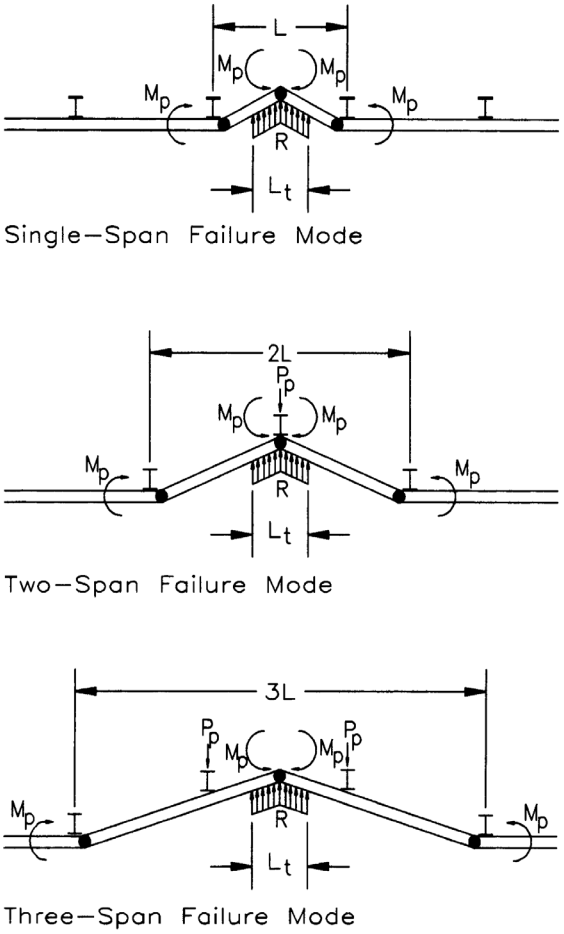

**Figure CA13.3.2-1—Possible Failure Modes for Post-and-Beam Railings**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- For failure modes involving an odd number of railing spans, $N$:

$$R = \frac{16M_p + (N-1)(N+1)P_pL}{2NL - L_t} \quad \text{(A13.3.2-1)}$$

- For failure modes involving an even number of railing spans, $N$:

$$R = \frac{16\,M_p + N^2 P_p L}{2NL - L_t} \quad \text{(A13.3.2-2)}$$

where:

$L$ = post spacing or single-span (ft)
$M_p$ = inelastic or yield line resistance of all of the rails contributing to a plastic hinge (kip-ft)
$M_{post}$ = plastic moment resistance of a single post (kip-ft)
$P_p$ = shear force on a single post which corresponds to $M_{post}$ and is located $\overline{Y}$ above the deck (kips)
$R$ = total ultimate resistance, i.e., nominal resistance, of the railing (kips)
$L_t$, $L_L$ = transverse length of distributed vehicle impact loads, $F_t$ and $F_L$ (ft)

For impact at the end of rail segments that causes the end post to fail, the critical rail nominal resistance, $R$, shall be calculated using Eq. A13.3.2-3.

- For any number of railing spans, $N$.

$$R = \frac{2M_p + 2P_pL\left(\sum_{i=1}^{N} i\right)}{2NL - L_t} \quad \text{(A13.3.2-3)}$$

This design procedure is applicable to concrete and metal post-and-beam railings.

The post on each end of the plastic mechanism must be able to resist the rail or beam shear.

For multiple-rail systems, each of the rails may contribute to the yield mechanism shown schematically in Figure CA13.3.2-1, depending on the rotation corresponding to its vertical position.

**A13.3.3—Concrete Parapet and Metal Rail**

**CA13.3.3**

The resistance of each component of a combination bridge rail shall be determined as specified in Articles A13.3.1 and A13.3.2. The flexural strength of the rail shall be determined over one span, $R_R$, and over two spans, $R'_R$. The resistance of the post on top of the wall, $P_p$, including the resistance of the anchor bolts or post, shall be determined.

The resistance of the combination parapet and rail shall be taken as the lesser of the resistances determined for the two failure modes shown in Figures A13.3.3-1 and A13.3.3-2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

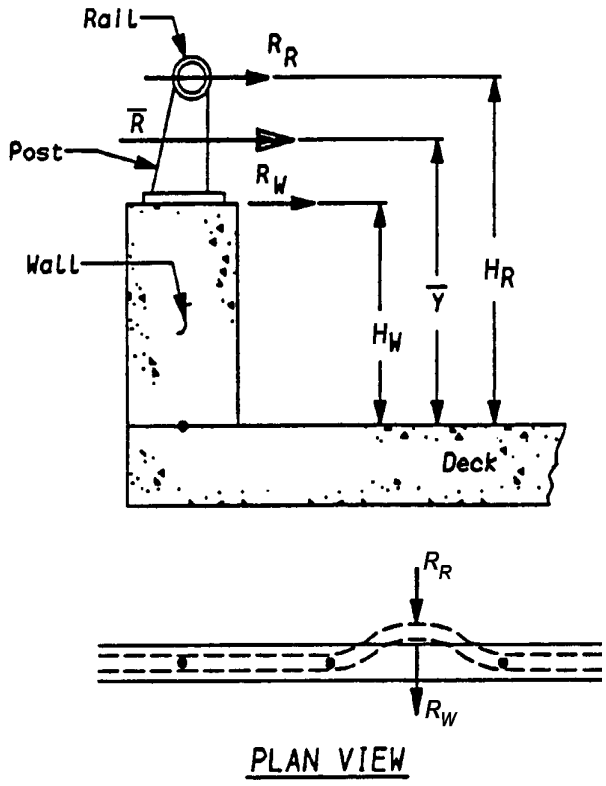

**Figure A13.3.3-1—Concrete Wall and Metal Rail Evaluation—Impact at Midspan of Rail**

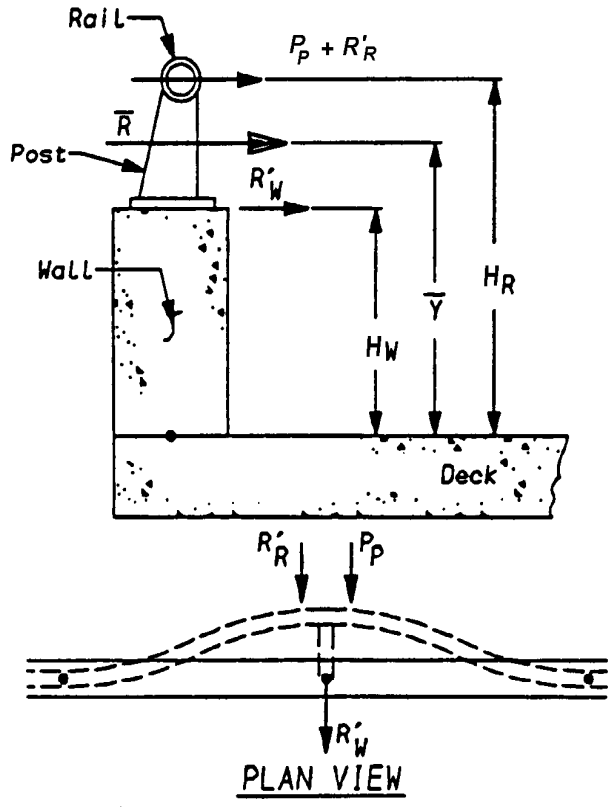

**Figure A13.3.3-2—Concrete Wall and Metal Rail Evaluation—Impact at Post**

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Where the vehicle impact is at midspan of the metal rail, as illustrated in Figure A13.3.3-1, the flexural resistance of the rail, $R_R$, and the maximum strength of the concrete wall, $R_w$, shall be added together to determine the combined resultant strength, $\overline{R}$ , and the effective height, $\overline{Y}$ , taken as:

$$\overline{R} = R_R + R_w \quad \text{(A13.3.3-1)}$$

$$\overline{Y} = \frac{R_R H_R + R_w H_w}{\overline{R}} \quad \text{(A13.3.3-2)}$$

where:

$R_R$ = ultimate capacity of rail over one span (kips)
$R_w$ = ultimate capacity of wall as specified in Article A13.3.1 (kips)
$H_w$ = height of wall (ft)
$H_R$ = height of rail (ft)

Where the vehicle impact is at a post, as illustrated in Figure A13.3.3-2, the maximum resultant strength, $\overline{R}$ , shall be taken as the sum of the post capacity, $P_p$, the rail strength, $R'_R$, and a reduced wall strength, $R'_w$, located at a height $\overline{Y}$ .

$$\overline{R} = P_p + R'_R + R'_w \quad \text{(A13.3.3-3)}$$

$$\overline{Y} = \frac{P_p H_R + R'_R H_R + R'_w H_w}{\overline{R}} \quad \text{(A13.3.3-4)}$$

in which:

$$R'_w = \frac{R_w H_w - P_p H_R}{H_w} \quad \text{(A13.3.3-5)}$$

where:

$P_p$ = ultimate transverse resistance of post (kips)
$R'_R$ = ultimate transverse resistance of rail over two spans (kips)
$R'_w$ = capacity of wall, reduced to resist post load (kips)
$R_w$ = ultimate transverse resistance of wall as specified in Article A13.3.1 (kips)

**A13.3.4—Wood Barriers**

Wood barriers shall be designed by elastic linear analysis with member sections proportioned on the basis of their resistances, specified in Section 8, using the strength limit states and the applicable load combinations specified in Table 3.4.1-1.

The commentary to Article CA13.2 applies.

It should also be recognized that a maximum effective height, $\overline{Y}$ , equal to the centroid rail height, $H_R$, could be obtained, but at a reduced resultant strength, $\overline{R}$ , equal to the post capacity, $P_p$ , and rail capacity, $R'_R$ , only.

The analysis herein does not consider impacts near open joints in the concrete wall or parapet. The metal rail will help distribute load across such joints. Improved rail resistance will be obtained if the use of expansion and contraction joints is minimized.

For impact near the end of railing segments, the nominal resistance may be calculated as the sum of the wall resistance, calculated using Eq. A13.3.1-3, and the metal rail resistance over one span, calculated using Eq. A13.3.2-3.

**CA13.3.4**

A limit or failure mechanism is not recommended for wood railings.

## A13.4—DECK OVERHANG DESIGN

### A13.4.1—Design Cases

Bridge deck overhangs shall be designed for the following design cases considered separately:

Design Case 1: the transverse and longitudinal forces specified in Table A13.2-1—Extreme Event Load Combination II limit state

Design Case 2: the vertical forces specified in Table A13.2-1—Extreme Event Load Combination II limit state

Design Case 3: the loads, specified in Article 3.6.1, that occupy the overhang—Load Combination Strength I limit state

For Design Cases 1 and 2, the load factor for dead load, $\gamma_p$, shall be taken as 1.0.

The total factored force effect shall be taken as:

$$Q = \sum \eta_i \gamma_i Q_i \qquad \text{(A13.4.1-1)}$$

where:

$\eta_i$ = load modifier specified in Article 1.3.2
$\gamma_i$ = load factors specified in Tables 3.4.1-1 and 3.4.1-2, unless specified elsewhere
$Q_i$ = force effects from loads specified herein

### A13.4.2—Decks Supporting Concrete Parapet Railings

For Design Case 1, the deck overhang may be designed to provide a flexural resistance, $M_s$, in kip-ft/ft which, acting coincident with the tensile force, $T$, in kip/ft, specified herein, exceeds $M_c$ of the parapet at its base. The axial tensile force, $T$, may be taken as:

$$T = \frac{R_w}{L_c + 2H} \qquad \text{(A13.4.2-1)}$$

where:

$R_w$ = parapet resistance specified in Article A13.3.1 (kips)
$L_c$ = critical length of yield line failure pattern (ft)
$H$ = height of wall (ft)
$T$ = tensile force per unit of deck length (kip/ft)

Design of the deck overhang for the vertical forces specified in Design Case 2 shall be based on the overhanging portion of the deck.

### CA13.4.2

If the deck overhang capacity is less than that specified, the yield line failure mechanism for the parapet may not develop as shown in Figure CA13.3.1-1, and Eqs. A13.3.1-1 and A13.3.1-2 will not be correct.

The crash testing program is oriented toward survival, not necessarily the identification of the ultimate strength of the railing system. This could produce a railing system that is significantly overdesigned, leading to the possibility that the deck overhang is also overdesigned.

All rights reserved. Duplication is a violation of applicable law.

## A13.4.3—Decks Supporting Post-and-Beam Railings

### A13.4.3.1—Overhang Design

For Design Case 1, the moment in kip-ft/ft, $M_d$, and tensile force, in kip/ft of deck, $T$, may be taken as:

$$M_d = \frac{12M_{post}}{W_b + d_b} \quad \text{(A13.4.3.1-1)}$$

$$T = \frac{12P_p}{W_b + d_b} \quad \text{(A13.4.3.1-2)}$$

For Design Case 2, the punching shear force and overhang moment may be taken as:

$$P_v = \frac{F_v L}{L_v} \quad \text{(A13.4.3.1-3)}$$

$$M_d = \frac{P_v X}{b} \quad \text{(A13.4.3.1-4)}$$

in which:

$$b = 2X + \frac{W_b}{12} \le L \quad \text{(A13.4.3.1-5)}$$

where:

$M_{post}$ = plastic moment resistance of a single post (kip-ft)
$P_p$ = shear force on a single post which corresponds to $M_{post}$ and is located $\overline{Y}$ above the deck (kips)
$X$ = distance from the outside edge of the post base plate to the section under investigation, as specified in Figure A13.4.3.1-1 (ft)
$W_b$ = width of base plate (in.)
$T$ = tensile force in deck (kip/ft)
$d_b$ = distance from the outer edge of the base plate to the innermost row of bolts, as shown in Figure A13.4.3.1-1 (in.)
$L$ = post spacing (ft)
$L_v$ = longitudinal distribution of vertical force $F_v$ on top of railing (ft)
$F_v$ = vertical force of vehicle laying on top of rail after impact forces $F_t$ and $F_L$ are over (kips)
$b$ = length of deck resisting post strength or shear load

### CA13.4.3.1

Vehicle collision on beam-and-post railing systems, such as a metal system with wide flange or tubular posts, imposes large concentrated forces and moments on the deck at the point where the post is attached to the deck.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

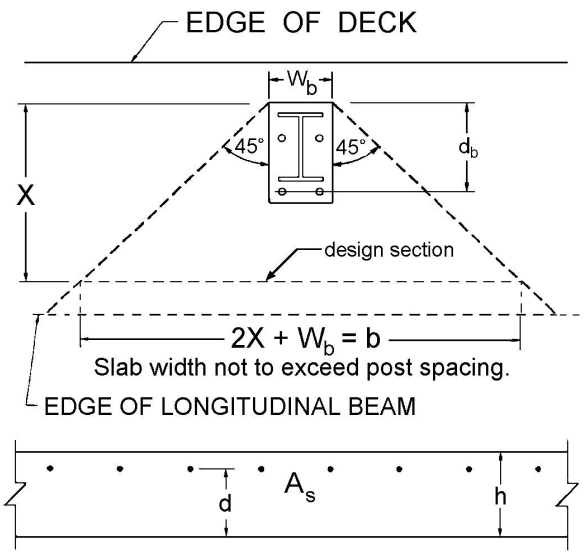

**Figure A13.4.3.1-1—Effective Length of Cantilever for Carrying Concentrated Post Loads, Transverse or Vertical**

Previous editions of the AASHTO *Standard Specifications for Highway Bridges* distributed railing or post loads to the slab using similar simplified analysis, e.g., "The effective length of slab resisting post loadings shall be equal to $E = 0.8x + 3.75$ ft where no parapet is used and equal to $E = 0.8x + 5.0$ ft where a parapet is used, where $x$ is the distance in ft from the center of the post to the point under investigation."

### A13.4.3.2—Resistance to Punching Shear

For Design Case 1, the factored shear may be taken as:

$$V_u = A_f F_y \qquad \text{(A13.4.3.2-1)}$$

The factored resistance of deck overhangs to punching shear may be taken as:

$$V_r = \phi V_n \qquad \text{(A13.4.3.2-2)}$$

$$V_n = v_c \left[ W_b + h + 2\left( E + \frac{B}{2} + \frac{h}{2} \right) \right] h \qquad \text{(A13.4.3.2-3)}$$

$$v_c = \left( 0.0633 + \frac{0.1265}{\beta_c} \right) \sqrt{f_c'} \le 0.1265 \sqrt{f_c'} \qquad \text{(A13.4.3.2-4)}$$

$$\frac{B}{2} + \frac{h}{2} \le B \qquad \text{(A13.4.3.2-5)}$$

in which:

$$\beta_c = W_b / d_b \qquad \text{(A13.4.3.2-6)}$$

where:

$V_u$ = factored shear force at section (kips)
$A_f$ = area of post compression flange (in.$^2$)
$F_y$ = yield strength of post compression flange (ksi)
$V_r$ = factored shear resistance (kips)
$V_n$ = nominal shear resistance of the section considered (kips)
$v_c$ = nominal shear resistance provided by tensile stresses in the concrete (ksi)
$W_b$ = width of base plate (in.)

**CA13.4.3.2**

Concrete slabs or decks frequently fail in punching shear resulting from the force in the compression flange of the post, $C$. Adequate thickness, $h$, edge distance, $E$, or base plate size ($W_b$ or $B$ or thickness) should be provided to resist this type of failure.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$h$ = depth of slab (in.)
$E$ = distance from edge of slab to centroid of compressive stress resultant in post (in.)
$B$ = distance between centroids of tensile and compressive stress resultants in post (in.)
$\beta_c$ = ratio of the long side to the short side of the concentrated load or reaction area
$f'_c$ = 28-day compressive strength of concrete (ksi)
$\phi$ = resistance factor = 1.0
$d_b$ = distance from the outer edge of the base plate to the innermost row of bolts (in.)

The assumed distribution of forces for punching shear shall be as shown in Figure A13.4.3.2-1.

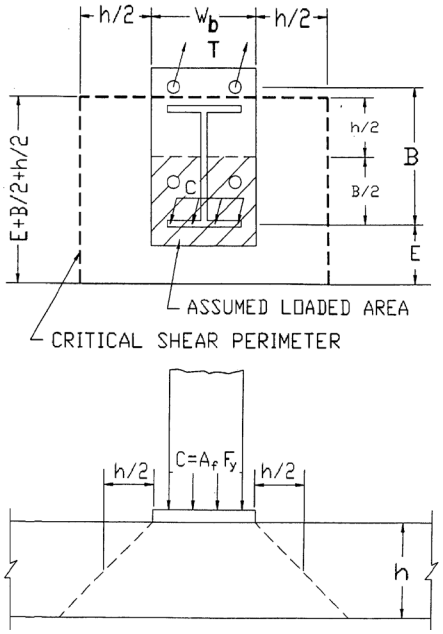

**Figure A13.4.3.2-1—Punching Shear Failure Mode**

Test results and in-service experience have shown that where deck failures have occurred, the failure mode has been a punching shear-type failure with loss of structural integrity between the concrete and reinforcing steel. Use of various types of shear reinforcement may increase the ultimate strength of the postdeck connection but is ineffective in reducing shear, diagonal tension, or cracking in the deck. Shear resistance can be increased by increasing the slab thickness, base plate width and depth, or edge distance.

SECTION 14

# JOINTS AND BEARINGS

## 14.1—SCOPE

This Section contains requirements for the design and selection of structural bearings and deck joints.

Units used in this Section shall be taken as kip, in., rad., °F, and Shore Hardness, unless otherwise noted.

## 14.2—DEFINITIONS

*Bearing*—A structural device that transmits loads while facilitating translation and/or rotation.

*Bearing Joint*—A deck joint provided at bearings and other deck supports to facilitate horizontal translation and rotation of abutting structural elements. It may or may not provide for differential vertical translation of these elements.

*Bronze Bearing*—A bearing in which displacements or rotations take place by the sliding of a bronze surface against a mating surface.

*Cotton-Duck-Reinforced Pad (CDP)*—A pad made from closely spaced layers of elastomer and cotton-duck, bonded together during vulcanization.

*Closed Joint*—A deck joint designed to prevent the passage of debris through the joint and to safeguard pedestrian and cycle traffic.

*Compression Seal*—A preformed elastomeric device that is precompressed in the gap of a joint with expected total range of movement less than 2.0 in.

*Construction Joint*—A temporary joint used to permit sequential construction.

*Cycle-Control Joint*—A transverse approach slab joint designed to permit longitudinal cycling of integral bridges and attached approach slabs.

*Damper*—A device that transfers and reduces forces between superstructure elements and/or superstructure and substructure elements, while permitting thermal movements. The device provides damping by dissipating energy under seismic, braking, or other dynamic loads.

*Deck Joint*—A structural discontinuity between two elements, at least one of which is a deck element. It is designed to permit relative translation and/or rotation of abutting structural elements.

*Disc Bearing*—A bearing that accommodates rotation by deformation of a single elastomeric disc molded from a urethane compound. It may be movable, guided, unguided, or fixed. Movement is accommodated by sliding of polished stainless steel on PFTE.

*Double Cylindrical Bearing*—A bearing made from two cylindrical bearings placed on top of each other with their axes at right angles to facilitate rotation about any horizontal axis.

*Fiberglass-Reinforced Pad (FGP)*—A pad made from discrete layers of elastomer and woven fiberglass bonded together during vulcanization.

*Fixed Bearing*—A bearing that prevents differential longitudinal translation of abutting structural elements. It may or may not provide for differential lateral translation or rotation.

*Integral Bridge*—A bridge without deck joints.

*Joint*—A structural discontinuity between two elements. The structural members used to frame or form the discontinuity.

All rights reserved. Duplication is a violation of applicable law.

*Joint Seal*—A poured or preformed elastomeric device designed to prevent moisture and debris from penetrating joints.

*Knuckle Bearing*—A bearing in which a concave metal surface rocks on a convex metal surface to provide rotation capability about any horizontal axis.

*Longitudinal*—Parallel with the main span direction of a structure.

*Longitudinal Joint*—A joint parallel to the span direction of a structure provided to separate a deck or superstructure into two independent structural systems.

*Metal Rocker or Roller Bearing*—A bearing that carries vertical load by direct contact between two metal surfaces and that accommodates movement by rocking or rolling of one surface with respect to the other.

*Modular Bridge Joint System (MBJS)*—A sealed joint with two or more elastomeric seals held in place by edgebeams that are anchored to the structural elements (deck, abutment, etc.) and one or more transverse centerbeams that are parallel to the edgebeams. Typically used for movement ranges greater than 4.0 in.

*Movable Bearing*—A bearing that facilitates differential horizontal translation of abutting structural elements in a longitudinal and/or lateral direction. It may or may not provide for rotation.

*Multirotational Bearing*—A bearing consisting of a rotational element of the pot type, disc type, or spherical type when used as a fixed bearing and that may, in addition, have sliding surfaces to accommodate translation when used as an expansion bearing. Translation may be constrained to a specified direction by guide bars.

*Neutral Point*—The point about which all of the cyclic volumetric changes of a structure take place.

*Open Joint*—A joint designed to permit the passage of water and debris through the joint.

*Plain Elastomeric Pad (PEP)*—A pad made exclusively of elastomer, which provides limited translation and rotation.

*Polytetrafluorethylene (PTFE)*—Also known as Teflon.

*Pot Bearing*—A bearing that carries vertical load by compression of an elastomeric disc confined in a steel cylinder and that accommodates rotation by deformation of the disc.

*Poured Seal*—A seal made from a material that remains flexible (asphaltic, polymeric, or other), which is poured into the gap of a joint and is expected to adhere to the sides of the gap. Typically used only when expected total range of movement is less than 1.5 in.

*PTFE Sliding Bearing*—A bearing that carries vertical load through contact stresses between a PTFE sheet or woven fabric and its mating surface, and that permits movements by sliding of the PTFE over the mating surface.

*Relief Joint*—A deck joint, usually transverse, that is designed to minimize either unintended composite action or the effect of differential horizontal movement between a deck and its supporting structural system.

*Restrainers*—A system of high-strength cables or rods that transfers forces between superstructure elements and/or superstructure and substructure elements under seismic or other dynamic loads after an initial slack is taken up, while permitting thermal movements.

*RMS*—Root Mean Square.

*Rotation about the Longitudinal Axis*—Rotation about an axis parallel to the main span direction of the bridge.

*Rotation about the Transverse Axis*—Rotation about an axis parallel to the transverse axis of the bridge.

*Sealed Joint*—A joint provided with a joint seal.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*Shock Transmission Unit (STU)*—A device that provides a temporary rigid link between superstructure elements and/or superstructure and substructure elements under seismic, braking, or other dynamic loads, while permitting thermal movements.

*Single-Support-Bar System (SSB)*—A MBJS designed so that only one support bar is connected to all of the centerbeams. The centerbeam/support bar connection typically consists of a yoke through which the support bar slides.

*Sliding Bearing*—A bearing that accommodates movement by translation of one surface relative to another.

*Steel-Reinforced Elastomeric Bearing*—A bearing made from alternate laminates of steel and elastomer bonded together during vulcanization. Vertical loads are carried by compression of the elastomer. Movements parallel to the reinforcing layers and rotations are accommodated by deformation of the elastomer.

*Strip Seal*—A sealed joint with an extruded elastomeric seal retained by edgebeams that are anchored to the structural elements (deck, abutment, etc). Typically used for expected total movement ranges from 1.5 to 4.0 in., although single seals capable of spanning a 5.0 in. gap are also available.

*Translation*—Horizontal movement of the bridge in the longitudinal or transverse direction.

*Transverse*—The horizontal direction normal to the longitudinal axis of the bridge.

*Waterproofed Joints*—Open or closed joints that have been provided with some form of trough below the joint to contain and conduct deck discharge away from the structure.

*Welded Multiple-Support-Bar System (WMSB)*—A MBJS designed so that each support bar is welded to only one centerbeam. Although some larger WMSB systems have been built and are performing well, WMSB systems are typically impractical for more than nine seals or for movement ranges larger than 27.0 in.

## 14.3—NOTATION

$A$ = plan area of elastomeric element or bearing (in.$^2$) (14.6.3.1)
$A_{Wbot}$ = area of weld at the bottom (in.$^2$) (14.5.6.9.7b)
$A_{Wmid}$ = minimum cross-sectional area of weld (in.$^2$) (14.5.6.9.7b)
$A_{Wtop}$ = area of weld at the top (in.$^2$) (14.5.6.9.7b)
$a_{cr}$ = creep deflection divided by initial dead load deflection (14.7.5.3.6)
$B_a$ = dimensionless coefficient used to determine peak hydrostatic stress (14.7.5.3.3)
$C_\alpha$ = parameter used to determine hydrostatic stress (14.7.5.3.3)
$c$ = minimum vertical clearance between rotating and nonrotating parts (in.); design clearance between piston and pot (in.) (C14.7.3.1) (14.7.4.7)
$D$ = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.); diameter of pad (in.); diameter of the bearing (in.) (14.7.3.2) (14.7.5.1) (14.7.6.3.6) (14.7.5.3.3) (14.7.5.3.4)
$D_a$ = dimensionless coefficient used to determine shear strain due to axial load (14.7.5.3.3)
$D_d$ = diameter of the disc element (in.) (14.7.8.1) (14.7.8.5)
$D_P$ = internal diameter of pot (in.) (14.7.4.3) (14.7.4.6) (14.7.4.7)
$D_r$ = dimensionless coefficient used to determine shear strain due to rotation (14.7.5.3.3)
$D_1$ = diameter of the rocker or roller surface (in.) (14.7.1.4)
$D_2$ = diameter of the mating surface, positive if the curvatures have the same sign, infinite if the mating surface is flat (in.) (14.7.1.4)
$d$ = diameter of rocker or roller (in.); the diameter of the hole or holes in the bearing (in.) (C14.7.1.4) (C14.7.5.1)
$d_{a1}$ = dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{a2}$ = dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{a3}$ = dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
$d_{cb}$ = depth of the centerbeam (in.) (14.5.6.9.7b)
$d_{sb}$ = depth of the support bar (in.) (14.5.6.9.7b)
$E_c$ = effective modulus of elastomeric bearing in compression (ksi)*;* uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad specific test data (ksi) (14.6.3.2) (14.7.6.3.3) (14.7.6.3.5b)
$E_s$ = Young's modulus for steel (ksi) (14.7.1.4)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$F_y$ = specified minimum yield strength of the weakest steel at the contact surface (ksi); yield strength of steel (ksi); yield strength of steel reinforcement (ksi) (14.7.1.4) (14.7.4.6) (14.7.4.7) (14.7.5.3.5)

$G$ = shear modulus of the elastomer (ksi); shear modulus of the CDP (14.6.3.1) (C14.6.3.2) (14.7.5.2) (14.7.5.3.3) (14.7.5.3.4) (C14.7.5.3.6) (14.7.6.2) (14.7.6.3.2) (14.7.6.3.4)

$H_{bu}$ = lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)

$H_s$ = horizontal load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.3.3)

$H_u$ = lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.7.4.7)

$h_{p1}$ = pot cavity depth (in.) (C14.7.4.3)

$h_{p2}$ = vertical clearance between top of piston and top of pot wall (in.) (C14.7.4.3)

$h_r$ = depth of elastomeric disc (in.) (14.7.4.3)

$h_{ri}$ = thickness of *i*th elastomeric layer (in.); thickness of *i*th internal elastomeric layer (in.); layer thickness for FGP which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (in.); thickness of a PEP (in.); mean thickness of two layers of elastomer bonded to the same reinforcement for FGP when the two layers are of different thicknesses (in.) (14.7.5.1) (14.7.5.3.6) (14.7.5.3.3) (14.7.5.3.5) (14.7.6.3.3) (14.7.6.3.7) (14.7.6.3.2)

$h_{rt}$ = total elastomer thickness (in.); smaller of total elastomer or bearing thickness (in.) (14.6.3.1) (14.6.3.2) (14.7.5.3.2) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.4)

$h_s$ = thickness of steel reinforcement (in.) (14.7.5.3.5)

$h_w$ = height of the weld (in.); height from top of rim to underside of piston (in.) (14.5.6.9.7b) (C14.7.4.3) (14.7.4.7)

$I$ = moment of inertia of plan shape of bearing (in.$^4$) (14.6.3.2)

$K$ = rotational stiffness of CDP (kip-in./rad.); bulk modulus (ksi) (C14.6.3.2) (C14.7.5.3.3)

$L$ = projected length of the sliding surface perpendicular to the rotation axis (in.); plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.); length of a CDP bearing pad in the plane of rotation (in.) (14.7.3.3) (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.5b) (14.7.6.3.6)

$M_H$ = horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.) (14.5.6.9.7b)

$M_{OT}$ = overturning moment range from horizontal reaction force (kip-in.) (14.5.6.9.7b)

$M_V$ = vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.); component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.) (14.5.6.9.7b)

$M_u$ = moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.) (14.6.3.2)

$m$ = modification factor (14.8.3.1) (5.6.5)

$n$ = number of interior layers of elastomer (14.7.5.3.3) (14.7.5.4) (14.7.6.1)

$P_D$ = compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip) (14.7.3.3)

$P_S$ = total compressive load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.1.4) (14.7.3.2)

$P_u$ = compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)

$p$ = allowable bearing at the service limit state (kip/in.) (C14.7.1.4)

$R$ = radius of curved sliding surface (in.) (14.6.3.2) (14.7.3.3)

$R_H$ = horizontal reaction force range in the connection (kip) (14.5.6.9.7b)

$R_o$ = radial distance from center of pot to object in question (e.g., pot wall, anchor bolt, etc.) (in.) (C14.7.4.3)

$R_V$ = vertical reaction force range in the connection (kip) (14.5.6.9.7b)

$S$ = shape factor of the CDP pad computed based on Eq. 14.7.5.1-1 and based on total pad thickness; shape factor of an individual elastomer layer; shape factor of PEP (14.6.3.2) (C14.7.5.3.6) (14.7.6.3.2)

$S_i$ = shape factor of the *i*th layer of an elastomeric bearing; shape factor of the *i*th internal layer of an elastomeric bearing; shape factor for FGP based upon an $h_{ri}$ layer thickness which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.5.4) (14.7.6.1) (14.7.6.3.2)

$S_{RB}$ = combined bending stress range in the centerbeam (ksi); bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi) (14.5.6.9.7b)

$S_{RZ}$ = vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi); vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi) (14.5.6.9.7b)

$S_{Wbot}$ = section modulus of the weld at the bottom for bending in the direction of the support bar axis (in.$^3$) (14.5.6.9.7b)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$S_{Wmid}$ = section modulus of the weld at the most narrow cross-section for bending in the direction normal to the centerbeam axis (in.$^3$) (14.5.6.9.7b)
$S_{Wtop}$ = section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in.$^3$) (14.5.6.9.7b)
$S_{Xcb}$ = vertical section modulus to the bottom of the centerbeam (in.$^3$) (14.5.6.9.7b)
$S_{Xsb}$ = vertical section modulus of the support bar to the top of the support bar (in.$^3$) (14.5.6.9.7b)
$S_{Ycb}$ = horizontal section modulus of the centerbeam (in.$^3$) (14.5.6.9.7b)
$t_b$ = pot base thickness (in.) (14.7.4.6) (14.7.4.7)
$t_p$ = total thickness of CDP pad (in.) (14.6.3.2) (14.7.6.3.5b)
$t_w$ = pot wall thickness (in.) (14.7.4.6) (14.7.4.7)
$W$ = roadway surface gap in a transverse deck joint, measured in the direction of travel at the extreme movement determined using the appropriate strength load combination specified in Table 3.4.1-1 (in.); width of the bearing (in.); length of cylinder (in.); length of cylindrical surface (in.); plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.) (14.5.3.2) (14.7.1.4) (14.7.3.2) (14.7.3.3) (14.7.5.1) (C14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.6)
$w$ = height of piston rim (in.) (14.7.4.7)
$\alpha$ = parameter used to determine hydrostatic stress (1/rad.) (14.7.5.3.3)
$\gamma_a$ = shear strain caused by axial load (14.7.5.3.3)
$\gamma_{a,cy}$ = shear strain caused by cyclic axial load (14.7.5.3.3)
$\gamma_{a,st}$ = shear strain caused by static axial load (14.7.5.3.3)
$\gamma_r$ = shear strain caused by rotation (14.7.5.3.3)
$\gamma_{r,cy}$ = shear strain caused by rotation from cyclic loads (14.7.5.3.3)
$\gamma_{r,st}$ = shear strain caused by rotation from static loads (14.7.5.3.3)
$\gamma_s$ = shear strain caused by shear displacement (14.7.5.3.3)
$\gamma_{s,cy}$ = shear strain caused by shear displacement from cyclic loads (14.7.5.3.3)
$\gamma_{s,st}$ = shear strain caused by shear displacement from static loads (14.7.5.3.3)
$\beta$ = angle between the vertical and resultant applied load (rad.) (14.7.3.3)
$\Delta F_{TH}$ = constant amplitude fatigue threshold taken from Table 6.6.1.2.5-3 for the detail category of interest (ksi); constant amplitude fatigue threshold for Category A as specified in Article 6.6 (14.5.6.9.7a) (14.7.5.3.5)
$\Delta f$ = force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi) (14.5.6.9.7a) (14.5.6.9.7b)
$\Delta_O$ = maximum horizontal displacement of the bridge superstructure at the service limit state (in.) (14.7.5.3.2)
$\Delta_S$ = maximum total shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.); maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.); maximum total static or cyclic shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.) (14.7.5.3.2) (14.7.6.3.4) (14.7.5.3.3)
$\Delta_T$ = design thermal movement range computed in accordance with Article 3.12.2 (in.) (14.7.5.3.2)
$\Delta_u$ = shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.) (14.6.3.1)
$\delta_d$ = initial dead load compressive deflection (in.) (14.7.5.3.6)
$\delta_L$ = instantaneous live load compressive deflection (in.) (14.7.5.3.6)
$\delta_{lt}$ = long-term dead load compressive deflection (in.) (14.7.5.3.6)
$\delta_u$ = vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.) (C14.7.4.3)
$\varepsilon$ = compressive strain in an elastomer layer (C14.7.5.3.6)
$\varepsilon_a$ = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.5.3.3) (14.7.5.4)
$\varepsilon_c$ = maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5b)
$\varepsilon_{di}$ = initial dead load compressive strain in $i$th elastomer layer (14.7.5.3.6)
$\varepsilon_{Li}$ = instantaneous live load compressive strain in $i$th elastomer layer (14.7.5.3.6)
$\varepsilon_s$ = average compressive strain due to total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.3)
$\varepsilon_t$ = maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5b)
$\theta_L$ = maximum rotation of the CDP pad at the service limit state (load factor = 1.0) due to live load (rad.) (14.7.6.3.5b)

© 2020 by the American Association of State Highway and Transportation Officials.

$\theta_s$ = maximum service limit state rotation due to total load for bearings unlikely to experience hard contact between metal components (rad.); maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.); maximum rotation of the CDP pad from applicable service load combinations in Table 3.4.1-1 (rad.); maximum service limit state design rotation angle about any axis of the pad specified in Article 14.4.2.1 (rad.); maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.); total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.) (C14.4.2) (14.4.2.1) (14.6.3.2) (14.7.6.3.5b) (14.7.5.3.3) (14.7.5.4)

$\theta_u$ = maximum strength limit state rotation for bearings that may experience hard contact between metal components (rad.); maximum strength limit state rotation for bearings which are less likely to experience hard contact between metal components (rad.); design rotation from applicable strength load combinations in Table 3.4.1-1 or Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.2 (rad.) (C14.4.2) (14.4.2.2.1) (14.4.2.2.2) (C14.7.3.1) (14.7.3.3) (14.7.4.3) (14.7.4.7) (14.7.8.1)

$\lambda$ = compressibility index (C14.7.5.3.3)

$\mu$ = coefficient of friction; coefficient of friction of the PTFE slider (14.6.3.1) (C14.7.8.4)

$\sigma$ = instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi) (C14.7.5.3.6)

$\sigma_{hyd}$ = peak hydrostatic stress (ksi) (14.7.5.3.3)

$\sigma_L$ = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi) (14.7.5.3.5) (14.7.6.3.2)

$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi); average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi) **;** average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi); total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.4.6) (14.7.5.3.4) (14.7.5.3.5) (14.7.6.3.2) (14.7.6.3.3) (14.7.6.3.4) (14.6.3.2) (14.7.6.3.5b) (14.7.5.3.3)

$\sigma_{SS}$ = maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi) (14.7.3.2) (14.7.3.3)

$\phi$ = resistance factor (14.6.1) (14.7.3.2) (C14.7.4.7)

$\phi_{tension}$ = resistance factor for tension for anchors governed by the steel (14.5.6.9.6)

$\phi_{shear}$ = resistance factor for shear for anchors governed by the steel (14.5.6.9.6)

$\phi_{A\ tension}$ = resistance factor for tension for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)

$\phi_{A\ shear}$ = resistance factor for shear for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)

$\phi_{B\ tension}$ = resistance factor for tension for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)

$\phi_{B\ shear}$ = resistance factor for shear for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)

$\Psi$ = subtended semiangle of the curved surface (rad.) (14.7.3.3)

## 14.4—MOVEMENTS AND LOADS

### 14.4.1—General

The selection and layout of the joints and bearings shall allow for deformations due to temperature and other time-dependent causes and shall be consistent with the proper functioning of the bridge.

Deck joints and bearings shall be designed to resist loads and accommodate movements at the service and strength limit states and to satisfy the requirements of the fatigue and fracture limit state. The loads induced on the joints, bearings, and structural members depend on the

**C14.4.1**

The joints and bearings should allow movements due to temperature changes, creep and shrinkage, elastic shortening due to prestressing, traffic loading, construction tolerances, or other effects. If these movements are restrained, large horizontal forces may result. If the bridge deck is cast-in-place or precast concrete, the bearings at a single support should permit transverse expansion and contraction. Externally applied transverse loads such as wind, earthquake, or traffic braking forces may be carried

stiffness of the individual elements and the tolerances achieved during fabrication and erection. These influences shall be taken into account when calculating design loads for the elements. No damage due to joint or bearing movement shall be permitted at the service limit state, and no irreparable damage shall occur at the strength limit state. At the extreme event limit state, bearings which are designed to act as fuses or sustain irreparable damage may be permitted by the Owner, provided loss of span is prevented.

Translational and rotational movements of the bridge shall be considered in the design of MBJS and bearings. The sequence of construction shall be considered, and all critical combinations of load and movement shall be considered in the design. Rotations about two horizontal axes and the vertical axis shall be considered. The movements shall include those caused by the loads, deformations, and displacements caused by creep, shrinkage, and thermal effects, and inaccuracies in installation. In all cases, both instantaneous and long-term effects shall be considered. The influence of dynamic load allowance shall be included for MBJS, but need not be included for bearings. The most adverse combination shall be tabulated for the bearings in a rational form such as shown in Figure C14.4.1-1.

For determining force effects in joints, bearings, and adjacent structural elements, the influence of their stiffnesses and the expected tolerances achieved during fabrication and erection shall be considered.

The three-dimensional effects of translational and rotational movements of the bridge shall be considered in the design of MBJS and bearings.

Both instantaneous and long-term effects shall be considered in the design of joints and bearings.

The effects of curvature, skew, rotations, and support restraint shall be recognized in the analysis.

The forces resulting from transverse or longitudinal prestressing of the concrete deck or steel girders shall be considered in the design of the bearings.

either on a small number of bearings near the centerline of the bridge or by an independent guide system. The latter is likely to be needed if the horizontal forces are large and fusing or irreparable damage is not permitted.

See Article C14.6.5.3 for discussion concerning bearings which are designed to act as fuses at the extreme event limit state.

Distribution of vertical load among bearings may adversely affect individual bearings. This is particularly critical when the girders are stiff in bending and torsion and bearings are stiff in compression, and the construction method does not allow minor misalignments to be corrected.

Bridge movements arise from a number of different causes. Simplified estimates of bridge movements, particularly on bridges with complex geometry, may lead to improper estimation of the direction of motion and, as a result, an improper selection of the bearing or joint system. Curved and skewed bridges have transverse as well as longitudinal movement due to temperature effects and creep or shrinkage. Transverse movement of the superstructure relative to the substructure may become significant for very wide bridges. Relatively wide curved and skewed bridges often undergo significant diagonal thermal movement, which introduces large transverse movements or large transverse forces if the bridge is restrained against such movements. Rotations caused by permissible levels of misalignment during installation should also be considered, and in many cases they will be larger than the live load rotations.

The neutral axis of a girder that acts compositely with its bridge deck is typically close to the underside of the deck. As a result, the neutral axis of the beam and the center of rotation of the bearing seldom coincide. Under these conditions, end rotation of the girder induces either horizontal movements or forces at the bottom flange or bearing level. The location of bearings off the neutral axes of the girders can also create horizontal forces due to elastic shortening of the girders when subjected to vertical loads at continuous supports.

The failure of bridge bearings or joint seals may ultimately lead to deterioration or damage to the bridge.

Each bearing and MBJS should be clearly identified in design documents, and all requirements should be identified. One possible format for this information is shown in Figure C14.4.1-1 for limit states other than extreme event.

When integral piers or abutments are used, the substructure and superstructure are connected such that additional restraints against superstructure rotation are introduced.

In curved bridges, thermal stresses are minimized when bearings are oriented such that they permit free translation along rays from a single point. With bearings arranged to permit such movement along these rays, there will be no thermal forces generated when the superstructure temperature changes uniformly. Any other

All rights reserved. Duplication is a violation of applicable law.

orientation of the bearings will induce thermal forces into the superstructure and substructure. However, other considerations often make orientation along rays from a single point impractical.

Prestressing of the deck causes changes in the vertical reactions due to the eccentricity of the forces, which creates restoring forces. Effects of creep and shrinkage also should be considered.

**Figure C14.4.1-1 (continued)—Typical Bridge Bearing Schedule**

### 14.4.2—Design Requirements

The minimum thermal movements shall be computed from the extreme temperature specified in Article 3.12.2 and the estimated setting temperatures. Design loads shall be based on the load combinations and load factors specified in Section 3.

### C14.4.2

Rotations are considered at the service and strength limit states as appropriate for different types of bearings. Bearings must accommodate movements in addition to supporting loads, so displacements, and in particular rotations, are needed for design. Live load rotations are typically less than 0.005 rad., but the total rotation due to

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

fabrication and setting tolerances for seats, bearings, and girders may be significantly larger than this. Therefore, the total design rotation is found by summing rotations due to dead and live load and adding allowances for profile grade effects and the tolerances described above. Article 14.8.2 specifies when a tapered plate shall be used if the rotation due to permanent load at the service limit state (load factor = 1.0) becomes excessive. An Owner may reduce the fabrication and setting tolerance allowances if justified by a suitable quality control plan; therefore, these tolerance limits are stated as recommendations rather than absolute limits.

Failure of deformable components such as elastomeric bearings is generally governed by a gradual deterioration under many cycles of load rather than sudden failure under a single load application. Further, the design limits for elastomeric bearings were originally developed under ASD service load conditions rather than the strength limit state loads considered during development of the high-load multirotational (HLMR) bearing systems. Unless smaller tolerances can be justified, $\theta_s$ for elastomeric components is the service limit state rotation plus 0.005 rad.

Metal or concrete components are susceptible to damage under a single rotation that causes metal-to-metal contact, and so they must be designed using the strength limit state rotations. Unless smaller tolerances can be justified, $\theta_u$ is the strength limit state rotation plus 0.01 rad.

Disc bearings are less likely to experience metal-to-metal contact than other HLMR bearings because the load element is unconfined. As a result, the total allowance for rotation is consequently smaller for a disc bearing than other HLMR bearings; however, the proof load test, as specified in the *AASHTO LRFD Bridge Construction Specifications*, assures against metal-to-metal contact.

#### 14.4.2.1—Elastomeric Pads and Steel Reinforced Elastomeric Bearings

The maximum service limit state rotation due to total load, $\theta_s$, for bearings unlikely to experience hard contact between metal components shall be taken as the sum of:

- the rotations from applicable service load combinations in Table 3.4.1-1, and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

The static and cyclic components of $\theta_s$ shall be considered separately when design is according to Article 14.7.5.3.3.

All rights reserved. Duplication is a violation of applicable law.

#### 14.4.2.2—High-Load Multirotational (HLMR) Bearings

*14.4.2.2.1—Pot Bearings and Curved Sliding Surface Bearings*

The maximum strength limit state rotation, $\theta_u$, for bearings such as pot bearings and curved sliding surfaces that may potentially experience hard contact between metal components shall be taken as the sum of:

- the rotations from applicable strength load combinations in Table 3.4.1-1;
- the maximum rotation caused by fabrication and installation tolerances, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value; and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

*14.4.2.2.2—Disc Bearings*

The maximum strength limit state rotation, $\theta_u$, for disc bearings which are less likely to experience hard contact between metal components due to their unconfined load element, shall be taken as the sum of:

- the rotations from applicable strength load combinations in Table 3.4.1-1, and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

## 14.5—BRIDGE JOINTS

### 14.5.1—Requirements

#### 14.5.1.1—General

**C14.5.1.1**

Deck joints shall consist of components arranged to accommodate the translation and rotation of the structure at the joint.

The type of joints and surface gaps shall accommodate the movement of motorcycles, bicycles, and pedestrians, as required, and shall neither significantly impair the riding characteristics of the roadway nor cause damage to vehicles.

The joints shall be detailed to prevent damage to the structure from water, deicing chemicals, and roadway debris.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Longitudinal deck joints shall be provided only where necessary to modify the effects of differential lateral and/or vertical movement between the superstructure and substructure.

Joints and joint anchors for grid and timber decks and orthotropic deck superstructures require special details.

**14.5.1.2—Structural Design**

Joints and their supports shall be designed to withstand force effects for the appropriate design limit state or states over the range of movements for the appropriate design limit state or states, as specified in Section 3. Resistance factors and modifiers shall be taken as specified in Sections 1, 5, 6, 7, and 8, as appropriate.

In snow regions, joint armor, armor connections, and anchors shall be designed to resist force effects that may be imposed on the joints by snagging snowplow blades. The edgebeams and anchorages of strip seals and MBJS with a skew exceeding 20 degrees in snow regions that do not incorporate protection methods such as those discussed in Article 14.5.3.3 shall be designed for the strength limit state with a minimum snowplow load acting as a horizontal line load on the top surface of the edgebeam in a direction perpendicular to the edgebeam of 0.12 kips/in. for a total length of 10.0 ft anywhere along the edgebeam in either direction. This load includes dynamic load allowance.

The following factors shall be considered in determining force effects and movements:

- properties of materials in the structure, including coefficient of thermal expansion, modulus of elasticity, and Poisson's ratio;
- effects of temperature, creep, and shrinkage;
- sizes of structural components;
- construction tolerances;
- method and sequence of construction;
- skew and curvature;
- resistance of the joints to movements;
- approach pavement growth;
- substructure movements due to embankment construction;
- foundation movements associated with the consolidation and stabilization of subsoils;
- structural restraints; and
- static and dynamic structural responses and their interaction.

To accommodate differential lateral movement, elastomeric bearings or combination bearings with the capacity for lateral movement should be used instead of longitudinal joints where practical.

**C14.5.1.2**

The strength limit state for the edgebeams of strip seals and MBJS and anchorage to the concrete or other elements should be checked with this snowplow load if the skew of the joint exceeds 20 degrees relative to a line transverse to the traveling direction. For smaller skews, the blades, which are skewed, will not strike an edgebeam all at once. Protection methods such as those discussed in Article 14.5.3.3 may eliminate the need to design for this snowplow load.

Snowplow blade angles vary regionally. Unless protection methods such as those discussed in Article 14.5.3.3 are used, agencies should avoid MBJS installations with skew that is within three degrees of the plow angle used in that region, to avoid having the plow drop into the gap between centerbeams.

The snowplow load was estimated from snowplow manufacturer information as the force required to deflect a spring-activated blade with 2.0 in. of compression and ten degrees of deflection. The snowplow load includes the effect of impact so the dynamic load allowance should not be applied. The snowplow load should be multiplied by the appropriate strength limit state load factor for live load.

Superstructure movements include those due to placement of bridge decks, volumetric changes, such as shrinkage, temperature, moisture and creep, passage of vehicular and pedestrian traffic, pressure of wind, and the action of earthquakes. Substructure movements include differential settlement of piers and abutments, tilting, flexure, and horizontal translation of wall-type abutments responding to the placement of backfill as well as shifting of stub abutments due to the consolidation of embankments and in-situ soils.

Any horizontal movement of a bridge superstructure will be opposed by the resistance of bridge bearings to movement and the rigidity or flexural resistance of substructure elements. The rolling resistance of rocker and rollers, the shear resistance of elastomeric bearings, or the frictional resistance of bearing sliding surfaces will oppose movement. In addition, the rigidity of abutments and the relative flexibility of piers of various heights and foundation types will affect the magnitude of bearing movement and the bearing forces opposing movement.

Rigid approach pavements composed of cobblestone, brick, or jointed concrete will experience growth or substantial longitudinal pressure due to restrained growth. To protect bridge structures from these potentially destructive pressures and to preserve the movement range of deck joints and the performance of joint seals, either

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The length of superstructure affecting the movement at one of its joints shall be the length from the joint being considered to the structure's neutral point.

For a curved superstructure that is laterally unrestrained by guided bearings, the direction of longitudinal movement at a bearing joint may be assumed to be parallel to the chord of the deck centerline taken from the joint to the neutral point of the structure.

The potential for unaligned longitudinal and rotational movement of the superstructure at a joint should be considered in designing the vertical joints in curbs and raised barriers and in determining the appropriate position and orientation of closure or bridging plates.

effective pavement pressure relief joints or pavement anchors should be provided in approach pavements, as described in *Transportation Research Record 1113.*

When horizontal movement at the ends of a superstructure is due to volumetric changes, the forces generated within the structure in resistance to these changes are balanced. The neutral point can be located by estimating these forces, taking into account the relative resistance of bearings and substructures to movement. The length of superstructure contributing to movement at a particular joint can then be determined.

**14.5.1.3—Geometry**

**C14.5.1.3**

The moving surfaces of the joint shall be designed to work in concert with the bearings to avoid binding the joints and adversely affecting force effects imposed on bearings.

For square or slightly skewed bridge layouts, moderate roadway grades at the joint and minimum changes in both horizontal and vertical joint alignment may be preferred in order to simplify the movements of joints and to enhance the performance of the structure.

**14.5.1.4—Materials**

**C14.5.1.4**

The materials shall be selected so as to ensure that they are elastically, thermally, and chemically compatible. Where substantial differences exist, material interfaces shall be formulated to provide fully functional systems.

Materials, other than elastomers, should have a service life of not less than 75 years. Elastomers for joint seals and troughs should provide a service life not less than 25 years.

Joints exposed to traffic should have a skid-resistant surface treatment, and all parts shall be resistant to attrition and vehicular impact.

Except for high-strength bolts, fasteners for joints exposed to deicing chemicals shall be made of stainless steel.

Preference should be given to those materials that are least sensitive to field compounding and installation variables and to those that can be repaired and altered by nonspecialized maintenance forces. Preference should also be given to those components and devices that will likely be available when replacements are needed.

**14.5.1.5—Maintenance**

**C14.5.1.5**

Deck joints shall be designed to operate with a minimum of maintenance for the design life of the bridge.

Detailing should permit access to the joints from below the deck and provide sufficient area for maintenance.

Mechanical and elastomeric components of the joint shall be replaceable.

Joints shall be designed to facilitate vertical extension to accommodate roadway overlays.

The position of bearings, structural components, joints, and abutment backwalls, and the configuration of pier tops should be chosen so as to provide sufficient space and convenient access to joints from below the deck. Inspection hatches, ladders, platforms, and/or catwalks shall be provided for the deck joints of large bridges not directly accessible from the ground.

## 14.5.2—Selection

### 14.5.2.1—Number of Joints

The number of movable deck joints in a structure should be minimized. Preference shall be given to continuous deck systems and superstructures and, where appropriate, integral bridges.

The need for a fully functional cycle-control joint shall be investigated on approaches of integral bridges.

Movable joints may be provided at abutments of single-span structures exposed to appreciable differential settlement. Intermediate deck joints should be considered for multiple-span bridges where differential settlement would result in significant overstresses.

### C14.5.2.1

Integral bridges, bridges without movable deck joints, should be considered where the length of superstructure and flexibility of substructures are such that secondary stresses due to restrained movement are controlled within tolerable limits.

Where a floorbeam design that can tolerate differential longitudinal movements resulting from relative temperature and live load response of the deck and independent supporting members, such as girders and trusses, is not practical, relief joints in the deck slab, movable joints in the stringers, and movable bearings between the stringers and floorbeams should be used.

Long-span deck-type structures with steel stringers that are slightly skewed, continuous, and composite can withstand substantial differential settlement without significant secondary stresses. Consequently, intermediate deck joints are rarely necessary for multiple-span bridges supported by secure foundations, i.e., piles, bedrock, dense subsoils, etc. Because the stresses induced by settlement can alter the point of inflection, a more conservative control of fatigue-prone detail locations is appropriate.

Guidance on the movements of the substructure can be found in Articles 10.5.2, 10.6.2, 10.7.2, and 10.8.2.

### 14.5.2.2—Location of Joints

Deck joints should be avoided over roadways, railroads, sidewalks, other public areas, and at the low point of sag vertical curves.

Deck joints should be positioned with respect to abutment backwalls and wingwalls to prevent the discharge of deck drainage that accumulates in the joint recesses onto bridge seats.

Open deck joints should be located only where drainage can be directed to bypass the bearings and discharged directly below the joint.

Closed or waterproof deck joints should be provided where joints are located directly above structural members and bearings that would be adversely affected by debris accumulation. Where deicing chemicals are used on bridge decks, sealed or waterproofed joints should be provided.

For straight bridges, the longitudinal elements of deck joints, such as plate fingers, curb and barrier plates, and modular bridge joint system support bars, should be placed parallel to the longitudinal axis of the deck. For curved and skewed structures, allowance shall be made for deck end movements consistent with that provided by the bearings.

Where possible, modular bridge joint systems should not be located in the middle of curved bridges to avoid unforeseeable movement demands. Preferably, modular bridge joint systems should not be located near traffic signals or toll areas so as to avoid extreme braking forces.

### C14.5.2.2

Open joints with drainage troughs should not be placed where the use of horizontal drainage conductors would be necessary.

End rotations of deck-type structures occur about axes that are roughly parallel to the centerline of bearings along the bridge seat. In skewed structures, these axes are not normal to the direction of longitudinal movement. Sufficient lateral clearances between plates, open joints, or elastomeric joint devices should be provided to prevent binding due to lack of alignment between longitudinal and rotational movements.

## 14.5.3—Design Requirements

### 14.5.3.1—Movements during Construction

Where practicable, construction staging should be used to delay construction of abutments and piers located in or adjacent to embankments until the embankments have been placed and consolidated. Otherwise, deck joints should be sized to accommodate the probable abutment and pier movements resulting from embankment consolidation after their construction.

Closure pours in concrete structures may be used to minimize the effect of prestress-induced shortening on the width of seals and the size of bearings.

**C14.5.3.1**

Where it is either desirable or necessary to accommodate settlement or other construction movements prior to deck joint installation and adjustment, the following construction controls may be used:

- placing abutment embankment prior to pier and abutment excavation and construction,
- surcharging embankments to accelerate consolidation and adjustment of in-situ soils,
- backfilling wall-type abutments up to sub-grade prior to placing bearings and backwalls above bridge seats, and
- using deck slab blockouts to allow placing the major portion of span dead loads prior to joint installation.

### 14.5.3.2—Design Movements

**C14.5.3.2**

A roadway surface gap, $W$, in in., in a transverse deck joint, measured in the direction of travel at the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1 shall satisfy:

- For a single gap:

$$W \le 4.0\,\text{in.} \qquad (14.5.3.2\text{-}1)$$

- For multiple modular gaps:

$$W \le 3.0\,\text{in.} \qquad (14.5.3.2\text{-}2)$$

For steel and nonprestressed wood superstructures, the minimum opening of a transverse deck joint and roadway surface gap therein shall not be less than 1.0 in. for movements determined using the appropriate strength load combination specified in Table 3.4.1-1. For concrete superstructures, consideration shall be given to the opening of joints due to creep and shrinkage that may require initial minimum openings of less than 1.0 in. at the strength limit state.

Unless more appropriate criteria are available, the maximum surface gap of longitudinal roadway joints shall not exceed 1.0 in. at the strength limit state.

At the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1, the opening between adjacent fingers on a finger plate shall not exceed:

- 2.0 in. for longitudinal openings greater than 8.0 in., or

Safe operation of motorcycles is one of the prime considerations in choosing the size of openings for finger plate joints.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- 3.0 in. for longitudinal openings 8.0 in. or less.

The finger overlap at the maximum movement shall be not less than 1.5 in. at the strength limit state.

Where bicycles are anticipated in the roadway, the use of special covering floor plates in shoulder areas shall be considered.

### 14.5.3.3—Protection

Deck joints shall be designed to accommodate the effects of vehicular traffic, pavement maintenance equipment, and other long-term environmentally induced damage.

Joints in concrete decks should be armored with steel shapes, weldments, or castings. Such armor shall be recessed below roadway surfaces and be protected from snowplows.

Jointed approach pavements shall be provided with pressure relief joints and/or pavement anchors. Approaches to integral bridges shall be provided with cycle-control pavement joints.

### C14.5.3.3

Snowplow protection for deck joint armor and joint seals may consist of any one of the following options:

- concrete buffer strips 12.0 to 18.0 in. wide with joint armor recessed 0.25 to 0.375 in. below the surface of such strips,
- tapered steel ribs protruding up to 0.50 in. above roadway surfaces to lift the plow blades as they pass over the joints,
- recesses in flexible pavement to position armor below anticipated rutting, but not so deep as to pond water.

Additional precautions to prevent damage by snowplows should be considered where the skew of the joints coincides with the skew of the plow blades, typically 30 degrees to 35 degrees.

### 14.5.3.4—Bridging Plates

Joint bridging plates and finger plates should be designed as cantilever members capable of supporting wheel loads at the strength limit state.

The differential settlement between the two sides of a joint bridging plate shall be investigated. If the differential settlement cannot be either reduced to acceptable levels or accommodated in the design and detailing of the bridging plates and their supports, a more suitable joint should be used.

Rigid bridging plates shall not be used at elastomeric bearings or hangers unless they are designed as cantilever members, and the contract documents require them to be installed to prevent binding of the joints due to horizontal and vertical movement at bearings.

### C14.5.3.4

Where binding of bridging plates can occur at bearing joints due to differential vertical translation of abutting structural elements or due to the longitudinal movement of bridging plates and bearings on different planes, the plates can be subjected to the total dead and live load superstructure reaction. Where bridging plates are not capable of resisting such loads, they may fail and become a hazard to the movement of vehicular traffic.

Thick elastomeric bearings responding to the application of vertical load or short hangers responding to longitudinal deck movements may cause appreciable differential vertical translation of abutting structural elements at bearing joints. To accommodate such movements, an appropriate type of sealed joint or a waterproofed open joint, rather than a structural joint with rigid bridging plates or fingers, should be provided.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 14.5.3.5—Armor

Joint-edge armor embedded in concrete substrates should be pierced by 0.75-in. minimum-diameter vertical vent holes spaced on not more than 18.0-in. centers.

Metal surfaces wider than 12.0 in. that are exposed to vehicular traffic shall be provided with an antiskid treatment.

### C14.5.3.5

Vent holes are necessary to help expel entrapped air and facilitate the attainment of a solid concrete substrate under joint edge armor.

The contract documents should require hand packing of concrete under joint armor.

### 14.5.3.6—Anchors

Armor anchors or shear connectors should be provided to ensure composite behavior between the concrete substrate and the joint hardware and to prevent subsurface corrosion by sealing the boundaries between the armor and concrete substrate. Anchors for edgebeams of strip seals and MBJS shall be designed for the snowplow load as required in Article 14.5.1.2.

Anchors for roadway joint armor shall be directly connected to structural supports or extended to effectively engage the reinforced concrete substrate. The free edges of roadway armor, more than 3.0 in. from other anchors or attachments, shall be provided with 0.50-in. diameter end-welded studs not less than 4.0 in. long spaced at not more than 12.0 in. from other anchors or attachments. The edges of sidewalk and barrier armor shall be similarly anchored.

### C14.5.3.6

Snow plow impact should also be considered in designing anchors.

### 14.5.3.7—Bolts

Anchor bolts for bridging plates, joint seals, and joint anchors shall be fully torqued high-strength bolts. The interbedding of nonmetallic substrates in connections with high-strength bolts shall be avoided. Cast-in-place anchors shall be used in new concrete. Expansion anchors, countersunk anchor bolts, and grouted anchors shall not be used in new construction.

### C14.5.3.7

Grouted anchors may be used for maintenance of existing joints.

## 14.5.4—Fabrication

Shapes or plates shall be of sufficient thickness to stiffen the assembly and minimize distortion due to welding.

To ensure appropriate fit and function, the contract documents should require that:

- joint components be fully assembled in the shop for inspection and approval,
- joints and seals be shipped to the jobsite fully assembled, and
- assembled joints in lengths up to 60.0 ft be furnished without intermediate field splices.

## C14.5.4

Joint straightness and fit of components should be enhanced by the use of shapes, bars, and plates 0.50 in. or thicker.

Construction procedures and practices should be developed to allow joint adjustment for installation temperatures without altering the orientation of joint parts established during shop assembly.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

## 14.5.5—Installation

### 14.5.5.1—Adjustment

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

For long structures, an allowance shall be included in the specified joint widths to account for the inaccuracies inherent in establishing installation temperatures and for superstructure movements that may take place during the time between the setting of the joint width and completion of joint installation. In the design of joints for long structures, preference should be given to those devices, details, and procedures that will allow joint adjustment and completion in the shortest possible time.

Connections of joint supports to primary members should allow horizontal, vertical, and rotational adjustments.

Construction joints and blockouts should be used where practicable to permit the placement of backfill and the major structure components prior to joint placement and adjustment.

### C14.5.5.1

Except for short bridges where installation temperature variations would have only a negligible effect on joint width, plans for each expansion joint should include required joint installation widths for a range of probable installation temperatures. For concrete structures, use of a concrete thermometer and measurement of temperature in expansion joints between superstructure units may be considered.

An offset chart for installation of the expansion joints is recommended to account for uncertainty in the setting temperature at the time of design. The designer may provide offset charts in appropriate increments and include the chart on the design drawings. Placement of the expansion joint hardware during deck forming should accommodate differences between setting temperature and an assumed design installation temperature.

Construction procedures that will allow major structure dead load movements to occur prior to placement and adjustment of deck joints should be used.

### 14.5.5.2—Temporary Supports

Deck joints shall be furnished with temporary devices to support joint components in proper position until permanent connections are made or until encasing concrete has achieved an initial set. Such supports shall provide for adjustment of joint widths for variations in installation temperatures.

### C14.5.5.2

Temporary attachments should be released to avoid damaging anchorage encasements due to movement of superstructures responding to rapid temperature changes.

For long structures with steel primary members, instructions should be included in the contract documents to ensure the removal of temporary supports or release of their connections as soon as possible after concrete placement.

### 14.5.5.3—Field Splices

Joint designs shall include details for transverse field splices for staged construction and for joints longer than 60.0 ft. Where practicable, splices should be located outside of wheel paths and gutter areas.

Details in splices should be selected to maximize fatigue life.

Field splices provided for staged construction shall be located with respect to other construction joints to provide sufficient room to make splice connections.

When a field splice is required, the contract documents should require that permanent seals not be placed until after joint installation has been completed. Where practicable, only those seals that can be installed in one continuous piece should be used.

### C14.5.5.3

Splices for less critical portions of joints or for lightly loaded joints should be provided with connections rigid enough to withstand displacement if joint armor is used as a form during concrete placement.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Where field splicing is unavoidable, splices should be vulcanized.

### 14.5.6—Considerations for Specific Joint Types

#### 14.5.6.1—Open Joints

Open deck joints shall permit the free flow of water through the joint. Open deck joints should not be used where deicing chemicals are applied. Piers and abutments at open joints shall satisfy the requirements of Article 2.5.2 in order to prevent the accumulation of water and debris.

#### C14.5.6.1

Under certain conditions, open deck joints can provide an effective and economical solution. In general, open joints are well-suited for secondary highways where little sand and salt are applied during the winter. They are not suited for urban areas where the costs of provisions for deck joint drainage are high.

Satisfactory performance depends upon an effective deck drainage system, control of deck discharge through joints, and containment and disposal of runoff from the site. It is essential that surface drainage and roadway debris not be permitted to accumulate on any part of the structure below such joints.

Protection against the deleterious effects of deck drainage may include shaping structural surfaces to prevent the retention of roadway debris and providing surfaces with deflectors, shields, covers, and coatings.

#### 14.5.6.2—Closed Joints

Sealed deck joints shall seal the surface of the deck, including curbs, sidewalks, medians, and, where necessary, parapet and barrier walls. The sealed deck joint shall prevent the accumulation of water and debris, which may restrict its operation. Closed or waterproof joints exposed to roadway drainage shall have structure surfaces below the joint shaped and protected as required for open joints.

Joint seals should be watertight and extrude debris when closing.

Drainage accumulated in joint recesses and seal depressions shall not be discharged on bridge seats or other horizontal portions of the structure.

Where joint movement is accommodated by a change in the geometry of elastomeric glands or membranes, the glands or membranes shall not come into direct contact with the wheels of vehicles.

#### C14.5.6.2

Completely effective joint seals have yet to be developed for some situations, particularly where there are severely skewed joints with raised curbs or barriers, and especially where joints are subjected to substantial movements. Consequently, some type of open or closed joint, protected as appropriate, should be considered instead of a sealed joint.

Sheet and strip seals that are depressed below the roadway surface and that are shaped like gutters will fill with debris. They may burst upon closing, unless the joints that they seal are extended straight to the deck edges where accumulated water and debris can be discharged clear of the structure. To allow this extension and safe discharge, it may be necessary to move the backwalls and bridge seats of some abutment types forward until the backwalls are flush with the wingwalls, or to reposition the wingwalls so that they do not obstruct the ends of the deck joints.

#### 14.5.6.3—Waterproofed Joints

Waterproofing systems for joints, including joint troughs, collectors, and downspouts, shall be designed to collect, conduct, and discharge deck drainage away from the structure.

In the design of drainage troughs, consideration should be given to:

- trough slopes of not less than 1.0 in./ft;
- open-ended troughs or troughs with large discharge openings;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- prefabricated troughs;
- troughs composed of reinforced elastomers, stainless steel, or other metal with durable coatings;
- stainless steel fasteners;
- troughs that are replaceable from below the joint;
- troughs that can be flushed from the roadway surface; and
- welded metal joints and vulcanized elastomeric splices.

**14.5.6.4—Joint Seals**

Seals shall accommodate all anticipated movements.

In the choice of a seal type, consideration should be given to seals that:

- are preformed or prefabricated;
- can be replaced without major joint modification;
- do not support vehicular wheel loads;
- can be placed in one continuous piece;
- are recessed below joint armor surface;
- are mechanically anchored; and
- respond to joint width changes without substantial resistance.

Elastomeric material for seals should be:

- durable, of virgin neoprene or natural rubber and reinforced with steel or fabric laminates;
- vulcanized;
- verified by long-term cyclic testing; and
- connected by adhesives that are chemically cured.

**14.5.6.5—Poured Seals**

Unless data supports a smaller joint width, the joint width for poured seals should be at least 6.0 times the anticipated joint movement determined using the appropriate strength load combination specified in Table 3.4.1-1.

Sealant bond to metal and masonry materials should be documented by national test methods.

**C14.5.6.5**

Poured seals should be used only for joints exposed to small movements and for applications where watertightness is of secondary importance.

**14.5.6.6—Compression and Cellular Seals**

Where seals with heavy webbing are exposed to the full movement range, joints shall not be skewed more than 20 degrees.

Compression seals for bearing joints shall not be less than 2.5 in. nor more than 6.0 in. wide when uncompressed and shall be specified in width increments in multiples of 0.5 in.

Primary roadway seals shall be furnished without splices or cuts, unless specifically approved by the

**C14.5.6.6**

Compression seals should be used only in those structures where the joint movement range can be accurately predicted.

Performance of compression and cellular seals is improved when concrete joint recesses are made by saw-cutting in a single pass, rather than by being cast with the aid of removable forms.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Engineer.

In gutter and curb areas, roadway seals shall be bent up in gradual curves to retain roadway drainage. Ends of roadway seals shall be protected by securely attached vented caps or covers. Secondary seals in curbs and barrier areas may be cut and bent as necessary to aid in bending and insertion into the joint.

Closed cell seals shall not be used in joints where they would be subjected to sustained compression, unless seal and adhesive adequacy have been documented by long-term demonstration tests for similar applications.

**14.5.6.7—Sheet and Strip Seals**

In the selection and application of either sheet or strip seals, consideration should be given to:

- joint designs for which glands with anchorages are not exposed to vehicular loadings;
- joint designs that allow complete closure without detrimental effects to the glands;
- joint designs where the elastomeric glands extend straight to the deck edges rather than being bent up at curbs or barriers;
- decks with sufficient crown or superelevation to ensure lateral drainage of accumulated water and debris;
- glands that are shaped to expel debris; and
- glands without abrupt changes in either horizontal or vertical alignment.

Sheet and strip seals should be spliced only when specifically approved by the Engineer.

**14.5.6.8—Plank Seals**

**C14.5.6.8**

Plank-type seals should not be used in joints with unpredictable movement ranges.

Application of plank seals should be limited to structures on secondary roads with light truck traffic, and that have unskewed or slightly skewed joints.

Consideration should be given to:

- seals that are provided in one continuous piece for the length of the joint;
- seals with splices that are vulcanized; and
- anchorages that can withstand the forces necessary to stretch or compress the seal.

**14.5.6.9—Modular Bridge Joint Systems (MBJS)**

*14.5.6.9.1—General*

*C14.5.6.9.1*

These Articles address the performance requirements, strength limit state design, and fatigue limit state design of modular bridge joint systems (MBJS).

These Specifications were developed primarily for,

These MBJS design specifications provide a rational and conservative method for the design of the main load-carrying steel components of MBJS. These Specifications do not specifically address the functional design of MBJS

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

and shall be applied to, the two common types of MBJS, which are multiple- and single-support-bar systems, including swivel-joist systems.

or the design of the elastomeric parts. These Specifications are based on research described in Dexter et al. (1997), which contains extensive discussion of the loads and measured dynamic response of MBJS and the fatigue resistance of common MBJS details. Fatigue test procedures were developed for the structural details as well.

Common types of MBJS are shown in Figures C14.5.6.9.1-1 through C14.5.6.9.1-3.

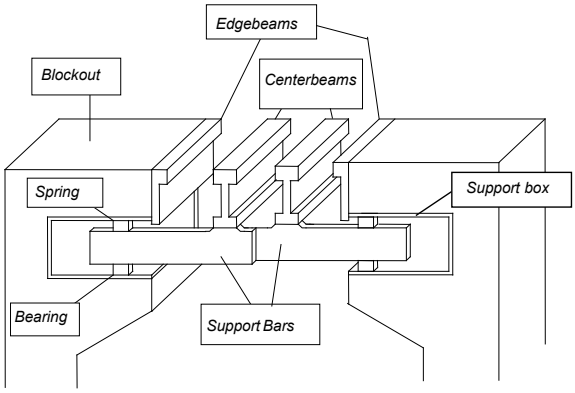

**Figure C14.5.6.9.1-1—Cut-away View of Typical Welded-multiple-support-bar (WMSB) Modular Bridge Joint System (MBJS) Showing Support Bars Sliding within Support Boxes**

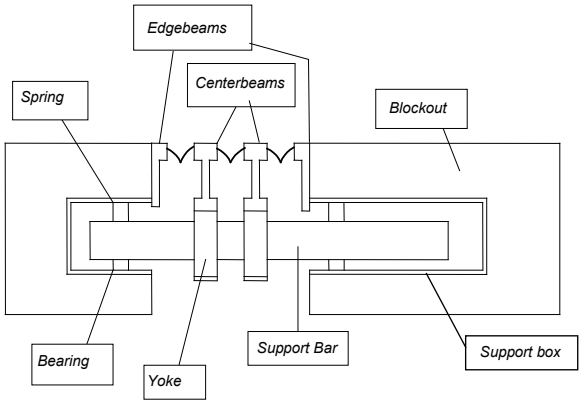

**Figure C14.5.6.9.1-2—Cross-Section View of Typical Single-support-bar (SSB) Modular Bridge Joint System (MBJS) Showing Multiple Centerbeams with Yokes Sliding on a Single Support Bar**

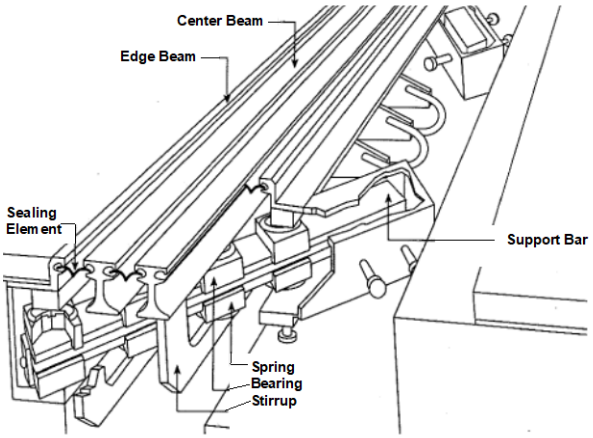

**Figure C14.5.6.9.1-3—Cut-away View of a "Swivel Joint," i.e., a Special Type of Single-support-bar (SSB) Modular Bridge Joint System (MBJS) with a Swiveling Single Support Bar**

*14.5.6.9.2—Performance Requirements*

The required minimum MBJS movement range capabilities for the six possible degrees of freedom given in Table 14.5.6.9.2-1 shall be added to the maximum movement and rotations calculated for the entire range of seals in the MBJS determined using the appropriate strength load combination specified in Table 3.4.1-1.

**Table 14.5.6.9.2-1—Additional Minimum Movement Range Capability for MBJS**

| Type of Movement | Minimum Design Movement Range* |
|---|---|
| Longitudinal Displacement | Estimated Movement + 1.0 in. |
| Transverse Movement | 1.0 in. |
| Vertical Movement | 1.0 in. |
| Rotation around Longitudinal Axis | 1° |
| Rotation Around Transverse Axis | 1° |
| Rotation Around Vertical Axis | 0.5° |

* Total movement ranges presented in the table are twice the plus or minus movement.

*C14.5.6.9.2*

The MBJS should be designed and detailed to minimize excessive noise or vibration during the passage of traffic.

A common problem with MBJS is that the seals fill with debris. Traffic passing over the joint can work the seal from its anchorage by compacting this debris. MBJS systems can eject most of this debris in the traffic lanes if the seals are opened to near their maximum opening. Therefore, it is prudent to provide for additional movement capacity.

MBJS should permit movements in all six degrees of freedom, i.e., translations in all three directions and rotations about all three axes. While it is mandatory to provide at least 1.0 in. movement in the longitudinal direction, as shown in Table 14.5.6.9.2-1, no more than 2.0 in. should be provided in addition to the maximum calculated movement if feasible. Also, more than 1.0 in. should not be added if it causes a further seal to be used. In the five degrees of freedom other than the longitudinal direction, the MBJS should provide the maximum calculated movement in conjunction with providing for at least the minimum additional movement ranges shown in Table 14.5.6.9.2-1. Half of the movement range shall be assumed to occur in each direction about the mean position. Some bridges may require greater than the additional specified minimum values.

The designer should consider showing the total estimated transverse and vertical movement in each direction, as well as the rotation in each direction about the three principal axes on the contract plans. Vertical movement due to vertical grade, with horizontal bearings, and vertical movement due to girder and rotation may also be considered.

All rights reserved. Duplication is a violation of applicable law.

Further design guidelines and recommendations can be found in Chapter 19 of the *AASHTO LRFD Bridge Construction Specifications* and Dexter et al. (1997).

*14.5.6.9.3—Testing and Calculation Requirements*

MBJS shall satisfy all test specifications detailed in Appendix A19 of the *AASHTO LRFD Bridge Construction Specifications*.

Each configuration of MBJS shall be designed for the strength and fatigue, and fracture limit states as specified in Articles 14.5.6.9.6 and 14.5.6.9.7.

*14.5.6.9.4—Loads and Load Factors*

Edgebeams, anchors, centerbeams, support bars, connections between centerbeams and support bars, support boxes, and connections, if any, to elements of the structure, such as girders, truss chords, crossbeams, etc., and other structural components shall be designed for the strength and fatigue and fracture limit states for the simultaneous application of vertical and horizontal axle loads. The edgebeams and anchors of MBJS in snow regions shall also be designed for the strength limit state for the snowplow load defined in Article 14.5.1.2. The design lane load need not be considered for MBJS.

The two wheel loads from each axle shall be centered 72.0 in. apart transversely. Each wheel load shall be distributed to the various edgebeams and centerbeams as specified in Article 14.5.6.9.5. The fraction of the wheel loads applied to each member shall be line loads applied at the center of the top surface of a member with a width of 20.0 in.

For the strength limit state, the vertical wheel loads shall be from the design tandem specified in Article 3.6.1.2.3; the wheel loads from the design truck in Article 3.6.1.2.2 need not be considered for the strength limit state of MBJS. Both of the tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical wheel load shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1.

The horizontal load for the strength limit state shall be 20 percent of the vertical wheel load ($LL + IM$), applied along the same line at the top surface of the centerbeam or edgebeam. For MBJS installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load.

To investigate the strength limit state, the axles shall be oriented and positioned transversely to maximize the force effect under consideration.

The vertical wheel load ranges for the fatigue limit state shall be from the largest axle load from the three-axle design truck specified in Article 3.6.1.2.2. For fatigue limit state design of MBJS, this axle load shall be considered as the total load on a tandem, i.e., the total load shall be split into two axle loads spaced

*C14.5.6.9.4*

The vertical axle load for fatigue limit state design is one-half the 32.0-kip axle load of the design truck specified in Article 3.6.1.2.2 or 16.0 kips. This reduction recognizes that the main axles of the design truck are a simplification of actual tandem axles. The simplification is not satisfactory for MBJS and other expansion joints because expansion joints experience a separate stress cycle for each individual axle.

For strength limit state design, there are two load combinations that could be considered. However, recognizing that each main axle of the design truck should actually be treated as 32.0-kip tandems, it is clear the 50.0-kip design tandem, which is not used for fatigue limit state design, will govern for strength limit state design.

The loads specified for fatigue limit state design actually represent load ranges. When these loads are applied to a structural analysis model with no dead load applied to the model, the moment, force, or stress that is computed everywhere represents a moment, force or stress range. In service, these stress ranges are partly due to the downward load and partly due to upward rebound from the dynamic impact effect.

The dynamic load allowance (impact factor) specified for deck joints of 75 percent was developed from field testing of MBJS conducted in Europe and was confirmed in field tests described in Dexter et al. (1997). The stress range due to the load plus this dynamic load allowance represents the sum of the downward part of that stress range and the upward part of the stress range due to rebound. Measurements, described in Dexter et al. (1997), showed that the maximum downward amplification of the static load is 32 percent, with about 31 percent rebound in the upward direction.

The vertical axle load range with impact for fatigue limit state design is one-half of the largest axle load of the design truck specified in Article 3.6.1.2.2, multiplied by 1.75 to include the dynamic load allowance, multiplied by a load factor of 1.5 (or 2.0 × 0.75), as specified in Table 3.4.1-1 for the Fatigue I case, or 42.0 kips. The 0.75 load factor transforms axles of an HS20 to those of an HS15 fatigue truck, which is

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

apart. Both of these tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical load range shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1. The load factors to consider shall be as specified in Table 3.4.1-1 for the Fatigue I case.

The horizontal load ranges for the fatigue limit state shall be at least 20 percent of the vertical wheel load range ($LL + IM$) for fatigue. For MBJS installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load range.

To investigate the fatigue limit state, the axles shall be oriented perpendicular to the travel direction only, but shall be positioned transversely to maximize the force effect under consideration. In bridges with a skew greater than 14 degrees, the two wheel loads from an axle may not be positioned on a centerbeam simultaneously, and the maximum stress ranges at a critical detail on the centerbeam may be the difference between the stresses due to the application of each wheel load separately.

presumed to represent the effective stress range. The factor 2.0 amplifies the effective stress range for the fatigue limit state to the presumed maximum expected stress range which with impact is required to be less than the fatigue threshold in Article 14.5.6.9.7a. It is the intent of the fatigue design specifications that the static load without impact considered (24.0 kips or 42.0 kips/1.75) should be infrequently exceeded, see Dexter et al. (1997).

Field measurements were taken at a variety of locations; so typical truck excitations should be reflected in the dynamic load allowance. However, a joint located on a structure with significant settlement or deterioration of the approach roadway may be exposed to a dynamic load allowance 20 percent greater due to dynamic excitation of the trucks.

MBJS with centerbeam spans less than 4.0 ft are reported to have lower dynamic effects (Pattis, 1993; Tschemmernegg and Pattis, 1994). The fatigue limit state design provisions of Article 14.5.6.9.7 happen to also limit the spans of typical 5.0-in.-deep centerbeams to around 4.0 ft anyway, so there is no need for a specific limitation of the span.

At sites with a tight horizontal curve (less than 490-ft radius) the vertical moments could be about 20 percent higher than would be expected. An increase in the dynamic load allowance for cases where there is a tight horizontal curve is not considered necessary if the speed of trucks on these curves is limited. In this case, the dynamic impact will be less than for trucks at full speed and the decreased dynamic impact will approximately offset the increased vertical load due to the horizontal curve.

The dynamic load allowance is very conservative when applied to the vertical load for strength limit state design, since in strength limit state design peak loads, not load ranges, are of interest. In the measurements made on MBJS in the field, the maximum downward vertical moment was only 1.32 times the static moment. There are usually no consequences of this conservative simplification since the proportions of the members are typically governed by fatigue and not strength.

The horizontal loads are taken as 20 percent of the vertical load plus the dynamic load allowance. In-service measurements, described in Dexter et al. (1997), indicate that the 20 percent horizontal load range is the largest expected from traffic at steady speeds, including the effect of acceleration and routine braking. The 20 percent horizontal load range for fatigue limit state design represents ten percent forward and ten percent backward.

Where strength limit state design is considered, the 20 percent horizontal load requirement corresponds to a peak load of 20 percent applied in one direction. percent horizontal peak load is appropriate for strength

*14.5.6.9.5—Distribution of Wheel Loads*

Each edgebeam shall be designed for 50 percent of the vertical and horizontal wheel loads specified in Article 14.5.6.9.4.

Table 14.5.6.9.5-1 specifies the centerbeam distribution factor, i.e., the percentage of the design vertical and horizontal wheel loads specified in Article 14.5.6.9.4 that shall be applied to an individual centerbeam for the design of that centerbeam and associated support bars. Distribution factors shall be interpolated for centerbeam top flange widths not given in the table, but in no case shall the distribution factor be taken as less than 50 percent. The remainder of the load shall be divided equally and applied to the two adjacent centerbeams or edgebeams.

**Table—14.5.6.9.5-1 Centerbeam Distribution Factors**

| Width of Centerbeam Top Flange | Distribution Factor |
|---|---|
| 2.5 in. (or less) | 50% |
| 3.0 in. | 60% |
| 4.0 in. | 70% |
| 4.75 in. | 80% |

limit state design. However, the field measurements, described in Dexter et al. (1997), show that the horizontal force effects resulting from extreme braking can be much greater than at steady speeds. Therefore, the 20 percent peak horizontal load represents the extreme braking for strength limit state design. For fatigue limit state design, these extreme events occur so infrequently that they do not usually need to be taken into account in most cases.

Special consideration should be given to the horizontal forces if the MBJS is located near a traffic light, stop sign, or toll facility or if the centerbeam is unusually wide.

*C14.5.6.9.5*

For the convenience of the designer, the vertical axle load range with impact for fatigue limit state design on one centerbeam 2.5 in. or less in width is 21.0 kips. On the centerbeam, each fraction of the wheel load of 10.5 kips is spaced 72.0 in. apart distributed over a width of 20.0 in. with a magnitude of 0.525 kips/in.

The distribution factor, i.e., the fraction of the design wheel load range assigned to a single centerbeam, is a function of applied load, tire pressure, gap width, and centerbeam height mismatch. Unfortunately, many of the factors affecting the distribution factor are difficult to quantify individually and even more difficult to incorporate in an equation or graph. Existing methods to estimate the distribution factor do not incorporate all of these variables and consequently can be susceptible to error when used outside the originally intended range. In view of this uncertainty, a simplified tabular method is used to estimate the distribution factor. Alternative methods are permitted if they are based on documented test data.

Wheel load distribution factors shown in Table 14.5.6.9.5-1 are based on field and laboratory testing, described in Dexter et al. (1997), and were found to be in acceptable agreement with the findings of other researchers. These distribution factors are based on the worst-case assumption of maximum joint opening (maximum gap width). Calculating the stress ranges at maximum gap opening is approximately 21 percent too conservative for fatigue limit state design. However, as explained in Dexter et al. (1997), this conservatism compensates for a lack of conservatism in the AASHTO fatigue design truck axle load.

For comparison to the fatigue threshold, the factored static axle load range, without the dynamic load allowance, would be 24.0 kips (or 42.0 kips/1.75, as discussed in Article C14.5.6.9.4). The static axle load range at the fatigue limit state is supposed to represent an axle load that is rarely exceeded. However, the fatigue limit state design load is multiplied by a distribution factor that is 21 percent too large, so in effect, this is equivalent to a static axle load range at the fatigue limit state of 29.0 kips that should be rarely exceeded, if correct distribution factors were used. This is more consistent with the statistics of weigh-in-

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

motion data where axle loads with exceedence levels of 0.01 percent were up to 36.0 kips, see Schilling (1990) or Nowak and Laman (1995).

A mitigating factor on the impact of these larger axle loads is that the distribution factor decreases with increasing axle load. Because of this effect, measurements reported in Dexter et al. (1997) show that as the axle load is increased from 24.0 to 36.0 kips, an increase of 50 percent, the load on one centerbeam increases from 12.6 to only 14.6 kips, an increase of only 16 percent.

Even though maximum gap opening occurs only rarely, it is an appropriate assumption for checking the Strength-I limit state. No additional conservatism is warranted in this case, however, because the dynamic load allowance is about 32 percent too conservative for strength limit state design only, as discussed in Article C14.5.6.9.

Another advantage of using the conservative distribution factors is that it may compensate for ignoring the effect of potential centerbeam height mismatch. Laboratory studies show that a height mismatch of 0.125 in. resulted in a 24 percent increase in the measured distribution factor, see Dexter et al. (1997). Although such mismatch is not common presently, and recent construction specifications are supposed to preclude this mismatch, it is prudent to anticipate that it may occur.

*14.5.6.9.6—Strength Limit State Design Requirements*

Where the MBJS is analyzed for the strength limit state, the gap between centerbeams shall be assumed to be at the fully opened position, typically 3.0 in.

The MBJS shall be designed to withstand the force effects for the strength limit state specified in Article 6.5.4 by applying the provisions of Articles 6.12 and 6.13, as applicable. All sections shall be compact, satisfying the provisions of Articles A6.1, A6.2, A6.3.2, and A6.3.3. MBJS shall be designed to withstand the load combination for the Strength I limit state that is specified in Table 3.4.1-1 for the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4. Dead loads need not be included. Loads shall be distributed as specified in Article 14.5.6.9.5.

Anchors shall be investigated at the strength limit state due to vertical wheel loads without the horizontal wheel loads using the requirements of Article 6.10.10.4.3. The anchors shall be checked separately for the horizontal wheel loads at the strength limit state. In snow regions, another separate analysis shall be performed for the anchors for the snowplow load defined in Article 14.5.1.2. Pullout or breakout at the strength limit state under each of these loads shall be investigated by the latest ACI 318 (*Building Code Requirements for Structural Concrete*), using the following resistance factors:

*C14.5.6.9.6*

Anchorage calculations for strength and fatigue limit states are presented in Dexter et al. (2002). A prescriptive design was found that satisfies the strength and fatigue limit state requirements presented in this specification, including the snowplow load. This design may be adopted without presenting explicit calculations. This design consists of a steel edgebeam minimum thickness 0.375 in. with Grade 50 (50.0 ksi yield) 0.5-in. diameter welded headed anchors (studs) with length of anchor of 6.0 in. spaced every 12.0 in. The welded headed anchor shall have minimum cover depth of 3.0 in., except where over the support boxes, where the cover depth is 2.0 in.

Analyzing the centerbeam as a continuous beam over rigid supports has been found to give good agreement with measured strains for loads in the vertical direction. For loads in the horizontal direction, the continuous beam model is conservative. For the loads in the horizontal direction, more accurate results can be achieved by treating the centerbeams and support bars as a coplanar frame pinned at the ends of the support bars.

Maximum centerbeam stresses in interior spans are typically generated with one of the wheel loads centered in the span. However, if the span lengths are the same, the exterior spans (first from the curb) will typically govern the design. In an optimum design, this exterior span should be about ten percent less than typical interior spans.

- For anchors governed by the steel, the resistance factors are:

  $\phi_{tension} = 0.80$
  $\phi_{shear} = 0.75$

- For anchors governed by the concrete, the load factors for Condition A, supplemental reinforcement in the failure area, are:

  $\phi_{A\ tension} = 0.85$
  $\phi_{A\ shear} = 0.85$

- For anchors governed by the concrete, the load factors for Condition B, no supplemental reinforcement, are:

  $\phi_{B\ tension} = 0.75$
  $\phi_{B\ shear} = 0.75$

*14.5.6.9.7—Fatigue Limit State Design Requirements*

*14.5.6.9.7a—General*

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall meet the fracture toughness requirements in Article 6.6.2. Bolts subject to tensile fatigue shall satisfy the provisions of Article 6.13.2.10.3.

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall be designed for the fatigue limit state as specified in Article 6.6.1.2 and as modified and supplemented herein.

Each detail shall satisfy:

$$\Delta f \le (\Delta F)_{TH} \qquad (14.5.6.9.7a\text{-}1)$$

where:

$\Delta f$ = force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi)

$\Delta F_{TH}$ = constant amplitude fatigue threshold taken from Table 6.6.1.2.5-3 for the detail category of interest (ksi)

The fatigue detail categories for the centerbeam-to-support-bar connection, shop splice, field splice, or other critical details shall be established by the fatigue testing as required by Article 14.5.6.9.3. All other details shall have been included in the test specimen. Details that did not

The vertical and horizontal wheel loads are idealized as line loads along the centerlines of the centerbeams, i.e., it is not necessary to take into account eccentricity of the forces on the centerbeam. The maximum reaction of the centerbeam against the support bar is generated when the wheel load is centered over the support bar. This situation may govern for the throat of the centerbeam/support bar weld, for design of the stirrup of a single-support-bar system, or for design of the support bar.

MBJS installed on skewed structures may require special attention in the design process.

*C14.5.6.9.7a*

The fatigue limit state strength of particular details in aluminum are approximately one-third the fatigue limit state strength of the same details in steel and, therefore, aluminum is typically not used in MBJS.

Yield strength and fracture toughness and weld quality have not been noted as particular problems for MBJS.

The design of the MBJS will typically be governed by the stress range at fatigue limit state critical details. The static strength limit state must also be checked according to the requirements of Article 14.5.6.9.6, but will typically not govern the design unless the total opening range and the support bar span is very large. Alternate design methods and criteria may be used if such methods can be shown through testing and/or analysis to yield fatigue-resistant and safe designs. The target reliability level for the fatigue limit state is 97.5 percent probability of no fatigue cracks over the lifetime of the MBJS.

Provisions are not included for a finite life fatigue limit state design (Fatigue II case, as defined in Article 3.4.1). Typically, most structures that require a modular expansion joint carry enough truck traffic to justify an infinite-life fatigue limit state design approach (Fatigue I case, as defined in Article 3.4.1). Furthermore, uncertainty regarding the number of axles per truck and the number of fatigue cycles per axle would make a finite life design approach difficult, and little cost is added to the MBJS by designing for infinite fatigue life.

The intent of this procedure is to assure that the stress range from the fatigue limit state load range is less than the CAFL and thereby ensuring essentially an infinite fatigue life.

crack during the fatigue test shall be considered noncritical. The fatigue detail categories for noncritical details shall be determined using Table 6.6.1.2.3-1.

Anchors and edgebeams shall be investigated for the fatigue limit state considering the force effects from vertical and horizontal wheel loads. Shear connectors and other anchors shall be designed for the fatigue limit state to resist the vertical wheel loads according to the provisions of Article 6.10.10.2 for the Fatigue I case defined in Article 3.4.1. The force effects from the horizontal wheel loads need not be investigated for standard welded headed anchors.

Edgebeams shall be at least 0.375 in. thick. Edgebeams with standard welded headed anchors spaced at most every 12.0 in. need not be investigated for in-plane bending for the fatigue limit state.

Fatigue-critical MBJS details include:

- the connection between the centerbeams and the support bars;
- connection of any attachments to the centerbeams (e.g., horizontal stabilizers or outriggers); and
- shop and/or field splices in the centerbeams.

MBJS details can in many cases be clearly associated with analogous details in the bridge design specifications. In other cases, the association is not clear and must be demonstrated through full-scale fatigue testing.

The detail of primary concern is the connection between the centerbeams and the support bars. A typical full-penetration welded connection, which was shown previously, can be associated with Category C. Fillet welded connections have very poor fatigue resistance and should not be allowed.

The bolted connections in single-support-bar MBJS usually involve a yoke or stirrup through which the support bar slides and/or swivels. Bolted connections should be classified as a Category B detail with respect to the bending stress range in the centerbeam, when designed as slip-critical using high-strength bolts that are pretensioned per Table 11.5.6.4.1-1 of the *AASHTO LRFD Bridge Construction Specifications*. In addition, the nuts should be locked after installation to prevent loss of pretention in the bolts. Other bolted connections should be classified as a Category D detail. As in any construction, more than one bolt must be used in bolted connections.

Field-welded splices of the centerbeams and edgebeams are also prone to fatigue. In new construction, it may be possible to make a full-penetration welded splice in the field before the joint is lowered into the blockout. However, in reconstruction work, the joint is often installed in several sections at a time to maintain traffic. In these cases, the splice must be made after the joint is installed. Because of the difficulty in access and position, obtaining a full-penetration butt weld in the field after the joint is installed may be difficult, especially if there is more than one centerbeam. Partial-penetration splice joints have inherently poor fatigue resistance and should not be allowed.

Bolted splices have been used and no cracking of these bolted splice details has been reported. The bolted splice plates behave like a hinge, i.e., they do not take bending moments. As a result, such details are subjected only to small shear stress ranges and need not be explicitly designed for the fatigue limit state. However, the hinge in the span creates greater bending moments at the support bar connection, therefore, the span with the field splice must be much smaller than the typical spans to reduce the applied stress ranges at the support bar connection. Moreover, lost bolts have been reported in the field at

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

these splice details, which if not detected in time can break the shear connection and result in cantilever centerbeams exhibiting unacceptable downward and rebound deflections under crossing vehicles. If bolted splices are used, the nuts should be locked after installation.

Thin stainless-steel slider plates are often welded like cover plates on the support bars. The fatigue strength of the ends of cover plates is Category E. However, there have not been any reports of fatigue cracks at these slider plate details in MBJS. The lack of problems may be because the support bar bending stress range is much lower at the location of the slider plate ends than at the centerbeam connection, which is the detail that typically governs the fatigue limit state design of the support bar. Also, it is possible that the fatigue strength is greater than that of conventional cover plates, perhaps because of the thinness of the slider plate. Often, the stainless-steel plates are extended to the end of the support bars, eliminating the Category E detail at the termination.

The fatigue limit state of the support bars or centerbeams should also be checked at the location of welded attachments that react against the horizontal equidistant devices, if provided. In addition to checking the equidistant device attachments with respect to the stress range in the support bar, there is also some bending load in the attachment itself. The equidistant devices take part of the horizontal load, especially in single-support-bar systems. The horizontal load is also transferred through friction in the bearings and springs of the centerbeam connection. However, since this transfer is influenced by the dynamic behavior of the MBJS, it is very difficult to quantify the load in the attachments.

These attachments are thoroughly tested in the Opening Movement Vibration Test required in Article 14.5.6.9.3. If the equidistant device attachments have no reported problems in the Opening Movement Vibration Test, they need not be explicitly designed as a loaded attachment for the fatigue limit state. If there were a fatigue problem with these attachments, it would be discovered in the Opening Movement Vibration Test.

*14.5.6.9.7b—Design Stress Range*

The design stress ranges, $\Delta f$, at all fatigue critical details shall be obtained from structural analyses of the modular joint system due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5. The MBJS shall be analyzed with a gap opening no smaller than the midrange configuration and no smaller than half of maximum gap opening. For each detail, the structural analysis shall include the worst-case position of the axle load to maximize the design stress range at that particular detail.

The nominal stress ranges, $\Delta f$, shall be calculated as follows for specific types of MBJS:

*C14.5.6.9.7b*

Since the design axle load and distribution factors represent a "worst case," the structural analysis for fatigue limit state design need not represent conditions worse than average. Therefore, for fatigue loading, the assumed gap can be equal to or greater than the midrange of the gap, typically 1.5 in., which is probably close to the mean or average opening. The gap primarily affects the support bar span.

See Article C14.5.6.9.6 for guidelines on the structural analysis. MBJS installed on skewed structures may require special attention in the design process.

On structures with joint skews greater than 14 degrees, it can be shown that the wheels at either end of an axle will not roll over a particular centerbeam

- Single-Support-Bar Systems
  - Centerbeam: The design bending stress range, $\Delta f$, in the centerbeam at a critical section adjacent to a welded or bolted stirrup shall be the sum of the stress ranges in the centerbeam resulting from horizontal and vertical bending at the critical section. The effects of stresses in any load-bearing attachments, such as the stirrup or yoke, need not be considered when calculating the stress range in the centerbeam. For bolted single-support-bar systems, stress ranges shall be calculated on the net section if the connections are not designed as slip-critical using high-strength bolts.
  - Stirrup: The design stress range, $\Delta f$, in the stirrup or yoke shall consider the force effects of the vertical reaction force range between the centerbeam and support bar. The stress range shall be calculated by assuming a load range in the stirrup that is greater than or equal to 30 percent of the total vertical reaction force range. The calculation of the design stress range in the stirrup or yoke need not consider the effects of stresses in the centerbeam. The effects of horizontal loads may be neglected in the fatigue limit state design of the stirrup.

- Welded Multiple-Support-Bar Systems
  - Centerbeam Weld Toe Cracking, i.e., Type A Cracking: The design stress range, $\Delta f$, for Type A cracking shall include the concurrent effects of vertical and horizontal bending stress ranges in the centerbeam, $S_{RB}$, and the vertical stress ranges in the top of the weld, $S_{RZ}$, as shown in Figure 14.5.6.9.7b-1. The design stress range for Type A cracking shall be determined as:

$$\Delta f = \sqrt{S_{RB}^{\ 2} + S_{RZ}^{\ 2}} \qquad (14.5.6.9.7b\text{-}1)$$

in which:

$$S_{RB} = \frac{M_V}{S_{xcb}} + \frac{M_H}{S_{Ycb}} \qquad (14.5.6.9.7b\text{-}2)$$

$$S_{RZ} = \frac{M_{OT}}{S_{Wtop}} + \frac{R_V}{A_{Wtop}} \qquad (14.5.6.9.7b\text{-}3)$$

$$M_{OT} = R_H d_{cb} \qquad (14.5.6.9.7b\text{-}4)$$

where:

simultaneously. This asymmetric loading could significantly affect the stress range at fatigue-sensitive details, either favorably or adversely. Nevertheless, a skewed centerbeam span is subjected to a range of moments that includes the negative moment from the wheel in the adjoining span, followed or preceded by the positive moment from the wheel in the span.

The stress states at the potential crack locations in these connections are multiaxial and very complicated. Simplified assumptions are used to derive the design stress range at the details of interest for common types of MBJS. Experience has shown that these simplified assumptions are sufficient provided that the same assumptions are applied in calculating the applied stress range for plotting the fatigue test data from which the design detail category was determined.

The design stress range should be estimated at a critical section at the weld toe. For example, Figure C14.5.6.9.7b-1 shows a typical moment diagram for the support bar showing the critical section. The support bar design bending stress range is a result of the sum of the bending moment created by the applied centerbeam reaction and the additional overturning moment developed by the horizontal force applied at the top of the centerbeam.

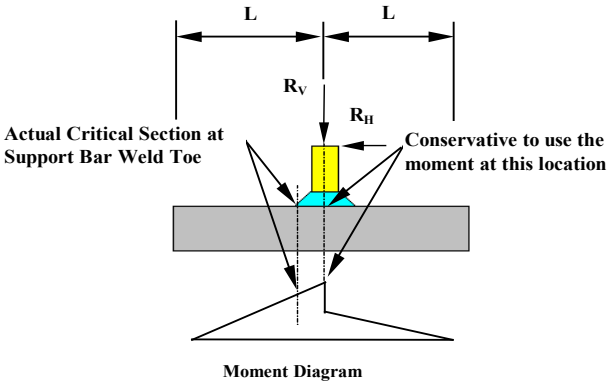

**Figure C14.5.6.9.7b-1—Typical Moment Diagram for a Support Bar**

It is conservative to estimate the moments at the centerline of the centerbeam as shown.

For all details except the welded-multiple-support-bar centerbeam-to-support-bar connection, the design stress range can be calculated using the design moment at the location of interest. Special equations for calculating the stress range are provided for welded multiple-support-bar MBJS. These special equations are based on cracking that has been observed in fatigue tests of welded multiple-support-bar MBJS. For the case of welded multiple-support bar centerbeam-to-support-bar connections, the design stress range is obtained by taking the square root of the sum of the squares of the horizontal stress ranges in the centerbeam or support bar and vertical stress ranges in the weld. Note this method of combining the stresses ignores the contribution of shear stresses in the region. Shear

$S_{RB}$ = combined bending stress range in the centerbeam (ksi)
$M_V$ = vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.)
$M_H$ = horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.)
$M_{OT}$ = overturning moment range from horizontal reaction force (kip-in.)
$S_{Xcb}$ = vertical section modulus to the bottom of the centerbeam (in.$^3$)
$S_{Ycb}$ = horizontal section modulus of the centerbeam (in.$^3$)
$S_{RZ}$ = vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi)
$R_V$ = vertical reaction force range in the connection (kip)
$R_H$ = horizontal reaction force range in the connection (kip)
$d_{cb}$ = depth of the centerbeam (in.)
$S_{Wtop}$ = section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in.$^3$)
$A_{Wtop}$ = area of weld at the top (in.$^2$)

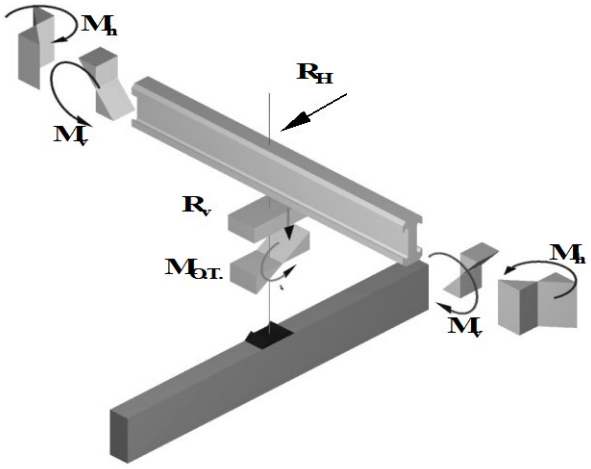

**Figure 14.5.6.9.7b-1—Force Effects Associated with Type A Cracking**

- Support Bar Weld Toe Cracking, i.e., Type B Cracking: The design stress range, $\Delta f$, for Type B cracking shall include the concurrent effects of vertical bending stress ranges in the support bar, $S_{RB}$, and the stresses are ignored in this procedure since they are typically small and very difficult to determine accurately. More details are provided in Dexter et al. (1997).

vertical stress ranges in bottom of the weld, $S_{RZ}$, as shown in Figure 14.5.6.9.7b-2. The design stress range, $\Delta f$, for Type B cracking shall be determined as:

$$\Delta f = \sqrt{S_{RB}^{\ 2} + S_{RZ}^{\ 2}} \qquad (14.5.6.9.7b\text{-}5)$$

in which:

$$S_{RB} = \frac{M_V}{S_{Xsb}} + \frac{1}{2}\frac{R_H\left(d_{cb} + h_w + \frac{1}{2}d_{sb}\right)}{S_{Xsb}} \qquad (14.5.6.9.7b\text{-}6)$$

$$S_{RZ} = \frac{R_H\left(d_{cb} + h_w\right)}{S_{Wbot}} + \frac{R_V}{A_{Wbot}} \qquad (14.5.6.9.7b\text{-}7)$$

where:

$S_{RB}$ = bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi)
$M_V$ = component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.)
$S_{Xsb}$ = vertical section modulus of the support bar to the top of the support bar (in.$^3$)
$h_w$ = height of the weld (in.)
$d_{sb}$ = depth of the support bar (in.)
$S_{RZ}$ = vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi)
$S_{Wbot}$ = section modulus of the weld at the bottom for bending in the direction of the support bar axis (in.$^3$)
$A_{Wbot}$ = area of weld at the bottom (in.$^2$)

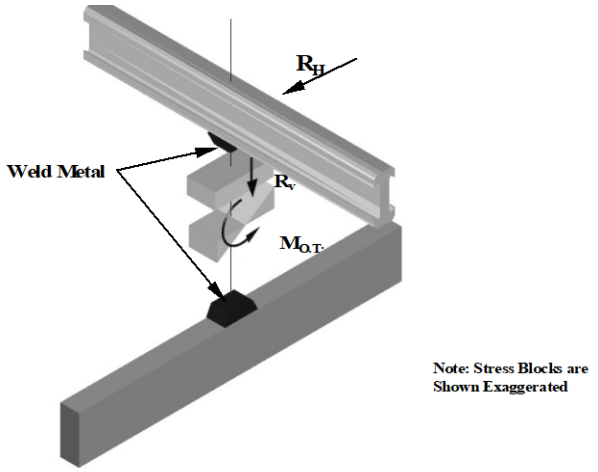

**Figure 14.5.6.9.7b-3—Force Effects Associated with Type C Cracking**

## 14.6—REQUIREMENTS FOR BEARINGS

### 14.6.1—General

Bearings may be fixed or movable as required for the bridge design. Movable bearings may include guides to control the direction of translation. Fixed and guided bearings shall be designed to resist all appropriate loads and restrain unwanted translation.

Unless otherwise noted, the resistance factor for bearings, $\phi$, shall be taken as 1.0.

Bearings subject to net uplift at any limit state shall be secured by tie-downs or anchorages.

The magnitude and direction of movements and the loads to be used in the design of the bearing shall be clearly defined in the contract documents.

Combinations of different types of fixed or movable bearings should not be used at the same expansion joint, bent, or pier, unless the effects of differing deflection and rotation characteristics on the bearings and the structure are accounted for in the design.

Multirotational bearings conforming to the provisions of this Section should not be used where vertical loads are less than 20 percent of the vertical bearing capacity.

All bearings shall be evaluated for component and connection strength and bearing stability.

Where two bearings are used at a support of box girders, the vertical reactions should be computed with consideration of torque resisted by the pair of bearings.

### C14.6.1

Bearings support relatively large loads while accommodating large translation or rotations.

The behavior of bearings is quite variable, and there is very little experimental evidence to precisely define $\phi$ for each limit state. $\phi$ is taken to be equal to 1.0 in many parts of Article 14.6 where a more refined estimate is not warranted. The resistance factors are often embedded in the design equations and based on judgment and experience, but they are generally thought to be conservative.

Differing deflection and rotational characteristics may result in damage to the bearings and/or structure.

Bearings loaded to less than 20 percent of their vertical capacity require special design (FHWA, 1991).

Bearings can provide a certain degree of horizontal load resistance by limiting the radius of the spherical surface. However, the ability to resist horizontal loads is a function of the vertical reaction on the bearing, which could drop during earthquakes or other extreme event loadings. In general, bearings are not recommended for horizontal to vertical load ratios of over 40 percent unless the bearings are intended to act as fuses or irreparable damage is permitted.

### 14.6.2—Characteristics

The bearing chosen for a particular application shall have appropriate load and movement capabilities. Table 14.6.2-1 and Figure 14.6.2-1 may be used as a guide when comparing the different bearing systems.

The following terminology shall apply to Table 14.6.2-1:

S = Suitable
U = Unsuitable
L = Suitable for limited applications
R = May be suitable, but requires special considerations or additional elements such as sliders or guideways
Long. = Longitudinal axis
Trans. = Transverse axis
Vert. = Vertical axis

### C14.6.2

Practical bearings will often combine more than one function to achieve the desired results. For example, a pot bearing may be combined with a PTFE sliding surface to permit translation and rotation.

Information in Table 14.6.2-1 is based on general judgment and observation, and there will obviously be some exceptions. Bearings listed as suitable for a specific application are likely to be suitable with little or no effort on the part of the Engineer other than good design and detailing practice. Bearings listed as unsuitable are likely to be marginal, even if the Engineer makes extraordinary efforts to make the bearing work properly. Bearings listed as suitable for limited application may work if the load and rotation requirements are not excessive.

**Table 14.6.2-1—Bearing Suitability**

| Type of Bearing | Movement | | Rotation about Bridge Axis Indicated | | | Resistance to Loads | | |
|---|---|---|---|---|---|---|---|---|
| | Long. | Trans. | Long. | Trans. | Vert. | Long. | Trans. | Vert. |
| Plain Elastomeric Pad | S | S | S | S | L | L | L | L |
| Fiberglass-reinforced Pad | S | S | S | S | L | L | L | L |
| Cotton-duck-reinforced Pad | U | U | U | U | U | L | L | S |
| Steel-reinforced Elastomeric Bearing | S | S | S | S | L | L | L | S |
| Plane Sliding Bearing | S | S | U | U | S | R | R | S |
| Curved Sliding Spherical Bearing | R | R | S | S | S | R | R | S |
| Curved Sliding Cylindrical Bearing | R | R | U | S | U | R | R | S |
| Disc Bearing | R | R | S | S | L | S | S | S |
| Double Cylindrical Bearing | R | R | S | S | U | R | R | S |

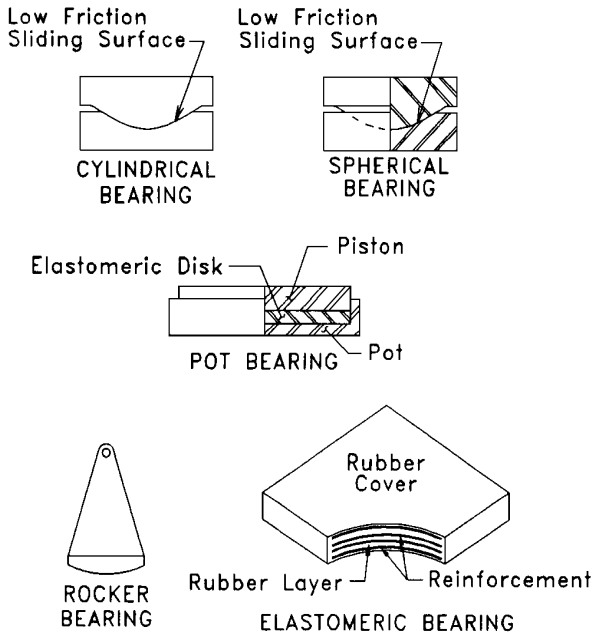

**Figure 14.6.2-1—Common Bearing Types**

## 14.6.3—Force Effects Resulting from Restraint of Movement at the Bearing

### 14.6.3.1—Horizontal Force and Movement

Horizontal forces and moments induced in the bridge by restraint of movement at the bearings shall be determined using the movements and bearing characteristics specified in Article 14.7. For bearings with elastomeric elements, these characteristics should include, but are not limited to, the consideration of increased shear modulus, $G$, at temperatures below 73°F.

Expansion bearings and their supports shall be designed in a manner such that the structure can undergo movements to accommodate the seismic and other extreme event displacement determined using the provisions in Section 3 without collapse. Adequate support length shall be provided for all bearings in accordance with Article 4.7.4.4.

The Engineer shall determine the number of bearings required to resist the loads specified in Section 3 with consideration of the potential for unequal participation due to tolerances, unintended misalignments, the capacity of the individual bearings, and the skew.

Consideration should be given to the use of field-adjustable elements to provide near simultaneous engagement of the intended number of bearings.

**C14.6.3.1**

Restraint of movement results in a corresponding force or moment in the structure. These force effects should be calculated taking into account the stiffness of the bridge and the bearings. The latter should be estimated by the methods outlined in Article 14.7. In some cases, the bearing stiffness depends on time and temperature, as well as on the movement. For example, the designer should take note that in cold temperatures which approach the appropriate minimum specified zone temperatures, the shear modulus, $G$, of an elastomer may be as much as four times that at 73°F. See Article 14.7.5.2 and AASHTO M 251 for more information.

Expansion bearings should allow sufficient movement in their unrestrained direction to prevent premature failure due to seismic and other extreme event displacements.

Often, bearings do not resist load simultaneously, and damage to only some of the bearings at one end of a span is not uncommon. When this occurs, high load concentrations can result at the location of the undamaged bearings, which should be taken into account. The number of bearings engaged should be based on type, design, and detailing of the bearings used, and on the bridge skew. Skew angles under 15 degrees are usually ignored. Skew

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

At the strength and extreme event limit states, horizontal forces transmitted to the superstructure and substructure by bearings, $H_{bu}$, shall be taken as those induced by sliding friction, rolling friction, or shear deformation of a flexible element in the bearing.

Sliding friction force shall be taken as:

$$H_{bu} = \mu P_u \quad (14.6.3.1\text{-}1)$$

where:

$H_{bu}$ = lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)
$\mu$ = coefficient of friction
$P_u$ = compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

The force due to the deformation of an elastomeric element shall be taken as:

$$H_{bu} = GA\frac{\Delta_u}{h_{rt}} \quad (14.6.3.1\text{-}2)$$

where:

$G$ = shear modulus of the elastomer (ksi)
$A$ = plan area of elastomeric element or bearing (in.$^2$)
$\Delta_u$ = shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.)
$h_{rt}$ = total elastomer thickness (in.)

Strength and extreme event limit states rolling forces shall be determined by testing.

angles over 30 degrees are usually considered significant and need to be considered in analysis. Skewed bridges have a tendency to rotate under seismic loading, and bearings should be designed and detailed to accommodate this effect.

Horizontal forces transmitted to other bridge elements by bearings do not include forces associated with the deformations of stiff bearing elements or hard metal-on-metal contact of bearing components because provisions in Article 14.7 are intended to avoid such contact.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

Special consideration should be given to bearings that support large horizontal loads relative to the vertical load (SCEF, 1991).

Eq. 14.6.3.1-1 is a function of vertical forces and friction, and is a measure of the maximum horizontal force which could be transmitted to the superstructure or substructure before slip occurs. Eq. 14.6.3.1-2 is also a measure of the maximum transmitted horizontal force, but is dependant primarily upon the shear modulus (stiffness) of the elastomer and applied lateral forces such as braking.

**14.6.3.2—Moment**

At the strength and extreme event limit states, both the substructure and superstructure shall be designed for the largest moment, $M_u$, transferred by the bearing.

For curved sliding bearings without a companion flat sliding surface, $M_u$ shall be taken as:

$$M_u = \mu P_u R \quad (14.6.3.2\text{-}1)$$

For curved sliding bearings with a companion flat sliding surface, $M_u$ shall be taken as:

**C14.6.3.2**

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The tangential force in curved sliding bearings is caused by friction resistance at the curved surface, and it acts about the center of the curved surface. $M_u$ is the moment due to this force that is transmitted by the bearing. The moment imposed on individual components of the bridge structure may be different from $M_u$ depending on the location of the axis of rotation and can be calculated by a rational method.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$$M_u = 2\mu P_u R \qquad (14.6.3.2\text{-}2)$$

where:

$M_u$ = moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.)
$R$ = radius of curved sliding surface (in.)

For unconfined elastomeric bearings and pads, $M_u$ shall be taken as:

$$M_u = 1.60(0.5E_cI)\frac{\theta_s}{h_{rt}} \qquad (14.6.3.2\text{-}3)$$

where:

$I$ = moment of inertia of plan shape of bearing (in.$^4$)
$E_c$ = effective modulus of elastomeric bearing in compression (ksi)
$\theta_s$ = maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.)
$h_{rt}$ = total elastomer thickness (in.)

For CDP, $M_u$ shall be taken as:

$$M_u = 1.25\left(4.5 - 2.2S + 0.6\sigma_s\right)\frac{E_cI}{t_p}\theta_s \qquad (14.6.3.2\text{-}4)$$

where:

$E_c$ = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)
$t_p$ = total thickness of CDP pad (in.)
$S$ = shape factor of the CDP pad computed based on Eq. 14.7.5.1-1 and based on total pad thickness
$\sigma_s$ = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

$\theta_s$ = maximum rotation of the CDP pad from applicable service load combinations in Table 3.4.1-1 (rad.)

The load–deflection curve of an elastomeric bearing is nonlinear, so $E_c$ is load dependent. One acceptable approximation for the effective modulus is:

$$E_c = 4.8GS^2 \qquad (C14.6.3.2\text{-}1)$$

where:

$S$ = shape factor of an individual elastomer layer
$G$ = shear modulus of the elastomer (ksi)

For a more precise approximation of effective modulus, the denominator of Eq. 14.7.5.3.3-15 may be used along with a calculated $B_a$ from Eq. C14.7.5.3.3-7 or Eq. C14.7.5.3.3-8.

The factor 1.60 in Eq. 14.6.3.2-3 is an average multiplier on total load on the bearing to estimate a strength limit state load, $M_u$, based on a service limit state rotation, $\theta_s$.

The factor 1.25 in Eq. 14.6.3.2-4 is a multiplier on total load on the bearing to estimate a strength limit state load, $M_u$, based on a service limit state rotation, $\theta_s$, and stress, $\sigma_s$.

The rotational stiffness, $K$, of CDP is provided by:

$$K = \left(4.5 - 2.2S + 0.6\sigma_s\right)\frac{E_cI}{t_p} \qquad (C14.6.3.2\text{-}2)$$

The moment, $M_u$, may be crucial for the design of CDP, because movable CDP are normally designed with PTFE sliding surfaces to develop the translational movement capacity. $M_u$ in the bearing pad results in edge bearing stress on the PTFE in addition to the average compressive stress. The PTFE on CDP pads is unconfined, and this moment may limit the bearing stress on the PTFE to a stress somewhat smaller than permitted on the CDP alone.

### 14.6.4—Fabrication, Installation, Testing, and Shipping

The provisions for fabrication, installation, testing, and shipping of bearings, specified in Section 18, "Bearing Devices," of the *AASHTO LRFD Bridge Construction Specifications*, shall apply.

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

**C14.6.4**

Some jurisdictions have provided additional guidance beyond that provided in the *AASHTO LRFD Bridge Construction Specifications* with respect to the fabrication, installation, testing, and shipping of multirotational-type bearings (SCEF, 1991).

Setting temperature is used in installing expansion bearings.

An offset chart for girder erection and alignment of the bearings is recommended to account for uncertainty in the setting temperature at the time of design. Offset charts should be defined in appropriate increments and included in the design drawings so that the position of the bearing can be adjusted to account for differences between setting temperature and an assumed design installation temperature.

### 14.6.5—Seismic and Other Extreme Event Provisions for Bearings

#### 14.6.5.1—General

This Article shall apply to the analysis, design, and detailing of bearings to accommodate the effects of earthquakes and, as appropriate, other extreme events for which the horizontal loading component is very large.

These provisions shall be applied in addition to all other applicable code requirements. The bearing-type selection shall consider the criteria described in Article 14.6.5.3 in the early stages of design.

**C14.6.5.1**

Extreme events other than earthquakes for which the horizontal loading component is very large include vehicle collisions, ship collisions, and high-velocity winds.

#### 14.6.5.2—Applicability

These provisions shall apply to pin, roller, rocker, and bronze or copper-alloy sliding bearings, elastomeric bearings, spherical bearings, and pot and disc bearings in common slab-on-girder bridges, but not to isolation-type bearings or structural fuse bearings designed primarily for the effects of extreme event dynamic horizontal loadings.

Although the strategy taken herein assumes that inelastic action is confined to properly detailed hinge areas in substructures, alternative concepts that utilize movement at the bearings to dissipate extreme event horizontal and/or vertical forces may also be considered. Where alternate strategies may be used, all ramifications of the increased movements and the predictability of the associated forces and transfer of forces shall be considered in the design and details.

**C14.6.5.2**

Provisions for the design, specification, testing, and acceptance of isolation bearings are given in the current AASHTO *Guide Specifications for Seismic Isolation Design*.

#### 14.6.5.3—Design Criteria

The selection, and the seismic or other extreme event horizontal loading design of bearings shall be related to the strength and stiffness characteristics of both the

**C14.6.5.3**

The commentary provided below specifically addresses seismic design considerations. However, it is also applicable to other extreme event horizontal

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

superstructure and the substructure.

Bearing design shall be consistent with the intended seismic or other extreme event response of the whole bridge system.

Where rigid-type bearings are used, the seismic or other horizontal extreme event forces from the superstructure shall be assumed to be transmitted through diaphragms or cross-frames and their connections to the bearings and then to the substructure without reduction due to local inelastic action along that load path. However, forces may be reduced in situations where the end-diaphragms in the superstructure have been specifically designed and detailed for inelastic action, in accordance with generally accepted provisions for ductile end-diaphragms.

As a minimum, bearings, restraints, and anchorages shall be designed to resist the forces specified in Article 3.10.9.

loadings such as vehicle and ship collisions, which are dynamic in nature but can have a very short duration. Accounting for the effects of other extreme events such as wind or waves may require special considerations that are not fully addressed in these specifications for bearing design.

Bearings have a significant effect on the overall seismic response of a bridge. They provide the seismic load transfer link between a stiff and massive superstructure and a stiff and massive substructure. As a result, very high (and difficult-to-predict) load concentrations can occur in the bearing components. The primary functions of the bearings are to resist the vertical loads due to dead load and live load and to allow for superstructure movements due to live load and temperature changes. Allowance for translation is made by means of rollers, rocker, or shear deformation of an elastomer, or through the provision of a sliding surface of bronze or copper alloy or PTFE. Allowance for rotation is made by hinges, confined or unconfined elastomers, or spherical sliding surfaces. Resistance to translation is provided by bearing components or additional restraining elements.

Historically, bearings have been very susceptible to seismic loads. Unequal loading during seismic events and much higher loads than anticipated have caused various types and levels of bearing damage. To allow movements, bearings often contain elements vulnerable to high loads and impacts.

The performance of bearings during past earthquakes needs to be evaluated in context with the overall performance of the bridge and the performance of the superstructure and substructure elements connected to the bearings. Rigid bearings have been associated with damage to the end cross-frames and the supporting pier or abutment concrete. In some cases, bearing damage and slippage has prevented more extensive damage.

The criteria for seismic design of bearings should consider the strength and stiffness characteristics of the superstructure and substructure. To minimize damage, the seismic load resisting system made of the end cross-frame or diaphragms, bearings, and substructure should allow a certain degree of energy dissipation, movement, or plastic deformation even if those effects are not quantified as they would be for seismic isolation bearings or structural fuses.

Based on their horizontal stiffness, bearings may be divided into four categories:

- rigid bearings that transmit seismic loads without any movement or deformations;
- deformable bearings that transmit seismic loads limited by plastic deformations or restricted slippage of bearing components;

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- seismic isolation type bearings that transmit reduced seismic loads, limited by energy dissipation; and
- structural fuses that are designed to fail at a prescribed load.

For the deformable-type bearing, limited and reparable bearing damage and displacement may be allowed for the design earthquake.

When both the superstructure and the substructure components adjacent to the bearing are very stiff, a deformable-type bearing should be considered.

Seismic isolation-type bearings should also be considered, and designed in accordance with the requirements of the current AASHTO *Guide Specifications for Seismic Isolation Design*.

Elastomeric bearings have been demonstrated to result in reduced force transmission to substructure.

A bearing may also be designed to act as a "structural fuse" that will fail at a predetermined load changing the articulation of the structure, possibly changing its period and hence seismic response, and probably resulting in increased movements. This strategy is permitted as an alternative to these provisions under Article 14.6.5.2. Such an alternative would require full consideration of forces and movements and of bearing repair/replacement details. It also requires the designer to address the inherent difficulty of detailing a structural element to fail reliably at predetermined load.

Elastomeric bearings having less than full rigidity, but not designed explicitly as seismic isolators or fuses, may be used under any circumstance. If used, they shall either be designed to accommodate imposed seismic or other horizontal extreme event loads, or, if survival of the elastomeric bearing itself is not required, other means such as restrainers, STUs, widened support lengths, or dampers shall be provided to prevent unseating of the superstructure.

## 14.7—SPECIAL DESIGN PROVISIONS FOR BEARINGS

### 14.7.1—Metal Rocker and Roller Bearings

#### 14.7.1.1—General

#### C14.7.1.1

Cylindrical bearings contain no deformable parts and are susceptible to damage if the superstructure rotates about an axis perpendicular to the axis of the bearing. Thus, they are unsuitable for bridges in which the axis of rotation may vary significantly under different situations, such as bridges with a large skew. They are also unsuitable for use in seismic regions because the transverse shear caused by earthquake loading can cause substantial overturning moment.

Good maintenance is essential if mechanical bearings are to perform properly. Dirt attracts and holds moisture, which, combined with high local contact stresses, can promote stress corrosion. Metal bearings, in particular, must be designed for easy maintenance.

Rockers can be suitable for applications in which the horizontal movement of the superstructure, relative to the substructure, is well within the available movement range after consideration of other applicable movements.

The rotation axis of the bearing shall be aligned with the axis about which the largest rotations of the supported member occur. Provision shall be made to ensure that the bearing alignment does not change during the life of the bridge. Multiple roller bearings shall be connected by gearing to ensure that individual rollers remain parallel to each other and at their original spacing.

Metal rocker and roller bearings shall be detailed so that they can be easily inspected and maintained.

Rockers should be avoided wherever practical and, when used, their movements and tendency to tip under seismic actions shall be considered in the design and details.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 14.7.1.2—Materials

Rocker and roller bearings shall be made of stainless steel conforming to ASTM A240, as specified in Article 6.4.7, or of structural steel conforming to AASHTO M 169 (ASTM A108), M 102M/M 102 (ASTM A668/A668M), or M 270M/M 270 (ASTM A709/A709M), Grades 36, 50, or 50W. Material properties of these steels shall be taken as specified in Tables 6.4.1-1 and 6.4.2-1.

### C14.7.1.2

Carbon steel has been the traditional steel used in mechanical bearings because of its good mechanical properties. Surface hardening may be considered. Corrosion resistance is also important. The use of stainless steel for the contact surfaces may prove economical when life-cycle costs are considered. Weathering steels should be used with caution as their resistance to corrosion is often significantly reduced by mechanical wear at the surface.

### 14.7.1.3—Geometric Requirements

The dimensions of the bearing shall be chosen taking into account both the contact stresses and the movement of the contact point due to rolling.

Each individual curved contact surface shall have a constant radius. Bearings with more than one curved surface shall be symmetric about a line joining the centers of their two curved surfaces.

If pintles or gear mechanisms are used to guide the bearing, their geometry should be such as to permit free movement of the bearing.

Bearings shall be designed to be stable. If the bearing has two separate cylindrical faces, each of which rolls on a flat plate, stability may be achieved by making the distance between the two contact lines no greater than the sum of the radii of the two cylindrical surfaces.

### C14.7.1.3

The choice of radius for a curved surface is a compromise: a large radius results in low contact stresses but large rotations of the point of contact and vice versa. The latter could be important if, for example, a rotational bearing is surmounted by a PTFE slider because the PTFE is sensitive to eccentric loading.

A cylindrical roller is in neutral equilibrium. The provisions for bearings with two curved surfaces achieves at least neutral, if not stable, equilibrium.

### 14.7.1.4—Contact Stresses

At the service limit state, the contact load, $P_S$, shall satisfy:

- For cylindrical surfaces:

$$P_S \le 8\frac{WD_1}{\left(1-\frac{D_1}{D_2}\right)}\left(\frac{F_y^{\,2}}{E_s}\right) \qquad (14.7.1.4\text{-}1)$$

- For spherical surfaces:

$$P_S \le 40\left(\frac{D_1}{1-\frac{D_1}{D_2}}\right)^2\frac{F_y^{\,3}}{E_s^{\,2}} \qquad (14.7.1.4\text{-}2)$$

where:

$D_1$ = diameter of the rocker or roller surface (in.)

### C14.7.1.4

The service limit state loads are limited so that the contact causes calculated shear stresses no higher than 0.55 $F_y$ or surface compression stresses no higher than 1.65 $F_y$. The maximum compressive stress is at the surface, and the maximum shear stress occurs just below it.

The formulas were derived from the theoretical value for contact stress between elastic bodies (Roark and Young, 1976). They are based on the assumption that the width of the contact area is much less than the diameter of the curved surface.

If two surfaces have curves of the opposite sign, the value of $D_2$ is negative. This would be an unusual situation in bridge bearings.

If careful inspection indicates that existing bearings which do not satisfy these provisions are performing well and there is no evidence of rutting or ridging, which may be evidence of local yielding, then reuse of the bearing may be viable. Evaluation of roller and rocker bearings with flat mating surfaces may proceed using the following historical provision:

Bearing per linear in. on expansion rockers and rollers at the service limit state shall not exceed the values obtained by the following formulas:

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

Diameters up to 25.0 in.

$$p = \frac{F_y - 13}{20}(0.6d) \qquad \text{(C14.7.1.4-1)}$$

Diameters 25.0 to 125.0 in.

$$p = \frac{F_y - 13}{20}3\sqrt{d} \qquad \text{(C14.7.1.4-2)}$$

where:

$p$ = allowable bearing at the service limit state (kip/in.)
$d$ = diameter of rocker or roller (in.)
$F_y$ = specified minimum yield strength of the weakest steel at the contact surface (ksi)

If loads are increased significantly by the rehabilitation or the mating surface is curved, complying with the current provisions may be more appropriate.

The two diameters have the same sign if the centers of the two curved surfaces in contact are on the same side of the contact surface, such as is the case when a circular shaft fits in a circular hole.

$D_2$ = diameter of the mating surface (in.) taken as:

- Positive if the curvatures have the same sign, and
- Infinite if the mating surface is flat.

$F_y$ = specified minimum yield strength of the weakest steel at the contact surface (ksi)
$E_s$ = Young's modulus for steel (ksi)
$W$ = width of the bearing (in.)

**14.7.2—PTFE Sliding Surfaces**

PTFE may be used in sliding surfaces of bridge bearings to accommodate translation or rotation. All PTFE surfaces other than guides shall satisfy the requirements specified herein. Curved PTFE surfaces shall also satisfy Article 14.7.3.

**C14.7.2**

PTFE is also known as TFE and is commonly used in bridge bearings in the United States. This Article does not cover guides. The friction requirements for guides are less stringent, and a wider variety of materials and fabrication methods can be used for them.

**14.7.2.1—PTFE Surface**

The PTFE surface shall be made from pure virgin PTFE resin satisfying the requirements of ASTM D4894 or D4895. It shall be fabricated as unfilled sheet, filled sheet, or fabric woven from PTFE and other fibers.

Unfilled sheets shall be made from PTFE resin alone. Filled sheets shall be made from PTFE resin uniformly blended with glass fibers, carbon fibers, or other chemically inert filler. The filler content shall not exceed 15 percent for glass fibers and 25 percent for carbon fibers.

Sheet PTFE may contain dimples to act as reservoirs for lubricant. Unlubricated PTFE may also contain dimples. Their diameter shall not exceed 0.32 in. at the

**C14.7.2.1**

PTFE may be provided in sheets or in mats woven from fibers. The sheets may be filled with reinforcing fibers to reduce creep, i.e., cold flow, and wear, or they may be made from pure resin. The friction coefficient depends on many factors, such as sliding speed, contact pressure, lubrication, temperature, and properties such as the finish of the mating surface (Campbell and Kong, 1987). The material properties that influence the friction coefficient are not well understood, but the crystalline structure of the PTFE is known to be important, and it is strongly affected by the quality control exercised during the manufacturing process.

Unfilled dimples can act as reservoirs for contaminants (dust, etc.) which can help to keep these contaminants from the contact surface.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

surface of the PTFE, and their depth shall be not less than 0.08 in. and not more than half the thickness of the PTFE. The reservoirs shall be uniformly distributed over the surface area and shall cover more than 20 percent but less than 30 percent of the contact surface. Dimples should not be placed to intersect the edge of the contact area. Lubricant shall be silicone grease, which satisfies Society of Automotive Engineers Specification SAE-AS8660.

Woven fiber PTFE shall be made from pure PTFE fibers. Reinforced woven fiber PTFE shall be made by interweaving high-strength fibers, such as glass, with the PTFE in such a way that the reinforcing fibers do not appear on the sliding face of the finished fabric.

**14.7.2.2—Mating Surface**

The PTFE shall be used in conjunction with a mating surface. Flat mating surfaces shall be stainless steel, and curved mating surfaces shall be stainless steel or anodized aluminum. Flat surfaces shall be stainless steel, Type 304, conforming to either ASTM A167 or A264, and shall be provided with a surface finish of 8.0 μ-in. RMS or better. Finishes on curved metallic surfaces shall not exceed 16.0 μ-in. RMS. The mating surface shall be large enough to cover the PTFE at all times.

**C14.7.2.2**

Stainless steel is the most commonly used mating surface for PTFE sliding surfaces. Anodized aluminum has been sometimes used in spherical and cylindrical bearings produced in other countries and may be considered if documentation of experience, acceptable to the Owner, is provided. The finish of this mating surface is extremely important because it affects the coefficient of friction. ASTM A240, Type 304, stainless steel, with a surface finish of 16.0 μ-in. RMS or better, is appropriate, but the surface measurements are inherently inexact, and hence it is not a specified alternative. Friction testing is required for the PTFE and its mating surface because of the many variables involved.

**14.7.2.3—Minimum Thickness**

*14.7.2.3.1—PTFE*

For all applications, the thickness of the PTFE shall be at least 0.0625 in. after compression. Recessed sheet PTFE shall be at least 0.1875 in. thick when the maximum dimension of the PTFE is less than or equal to 24.0 in., and 0.25 in. when the maximum dimension of the PTFE is greater than 24.0 in. Woven fabric PTFE, which is mechanically interlocked over a metallic substrate, shall have a minimum thickness of 0.0625 in. and a maximum thickness of 0.125 in. over the highest point of the substrate.

*C14.7.2.3.1*

A minimum thickness is specified to ensure uniform bearing and to allow for wear.

During the first few cycles of movement, small amounts of PTFE transfer to the mating surface and contribute to the very low friction achieved subsequently. This wear is acceptable and desirable.

PTFE continues to wear with time (Campbell and Kong, 1987) and movement; wear is exacerbated by deteriorated or rough surfaces. Wear is undesirable because it usually causes higher friction and reduces the thickness of the remaining PTFE. Unlubricated, flat PTFE wears more severely than the lubricated material. The evidence on the rate of wear is tentative. High travel speeds, such as those associated with traffic movements, appear to be more damaging than the slow ones due to thermal movements. However, they may be avoided by placing the sliding surface on an elastomeric bearing that will absorb small longitudinal movements. No further allowance for wear is made in this Specification due to the limited research available to quantify or estimate the wear as a function of time and travel. However, wear may ultimately cause the need for

*14.7.2.3.2—Stainless Steel Mating Surfaces*

The thickness of the stainless steel mating surface shall be at least 16 gauge when the maximum dimension of the surface is less than or equal to 12.0 in. and at least 13 gauge when the maximum dimension is larger than 12.0 in.

Backing plate requirements shall be taken as specified in Article 14.7.2.6.2.

*C14.7.2.3.2*

The minimum thickness requirements for the mating surface are intended to prevent it from wrinkling or buckling. This surface material is usually quite thin to minimize the cost of the highly finished mating surface. Some mating surfaces, particularly those with curved surfaces, are made of carbon steel on which a stainless steel weld is deposited. This welded surface is then finished and polished to achieve the desired finish. Some jurisdictions require a minimum thickness of 0.094 in. for welded overlay after grinding and polishing.

**14.7.2.4—Contact Pressure**

The contact stress between the PTFE and the mating surface shall be determined at the service limit state using the nominal area.

The average contact stress shall be computed by dividing the load by the projection of the contact area on a plane perpendicular to the direction of the load. The contact stress at the edge shall be determined by taking into account the maximum moment transferred by the bearing assuming a linear distribution of stress across the PTFE.

Stresses shall not exceed those given in Table 14.7.2.4-1. Permissible stresses for intermediate filler contents shall be obtained by linear interpolation within Table 14.7.2.4-1.

**C14.7.2.4**

The average contact stress shall be determined by dividing the load by the projection of the contact area onto a plane perpendicular to the direction of the load. The edge contact stress shall be determined based on the service limit state load and the maximum service limit state moment transferred by the bearing.

The contact pressure must be limited to prevent excessive creep or plastic flow of the PTFE, which causes the PTFE disc to expand laterally under compressive stress and may contribute to separation or bond failure. The lateral expansion is controlled by recessing the PTFE into a steel plate or by reinforcing the PTFE, but there are adverse consequences associated with both methods. Edge loading may be particularly detrimental because it causes large stress and potential flow in a local area near the edge of the material in hard contact between steel surfaces. The average and edge contact pressure in Table 14.7.2.4-1 are in appropriate proportions to one another relative to the currently available research. Better data may become available in the future. These are in the lower range of those used in Europe.

**Table 14.7.2.4-1—Maximum Contact Stress for PTFE at the Service Limit State (ksi)**

| Material | Average Contact Stress (ksi) | | Edge Contact Stress (ksi) | |
|---|---|---|---|---|
| | Permanent Loads | All Loads | Permanent Loads | All Loads |
| Unconfined PTFE: | | | | |
| Unfilled Sheets | 1.5 | 2.5 | 2.0 | 3.0 |
| Filled Sheets with Maximum Filler Content | 3.0 | 4.5 | 3.5 | 5.5 |
| Confined Sheet PTFE | 3.0 | 4.5 | 3.5 | 5.5 |
| Woven PTFE Fiber over a Metallic Substrate | 3.0 | 4.5 | 3.5 | 5.5 |
| Reinforced Woven PTFE over a Metallic Substrate | 4.0 | 5.5 | 4.5 | 7.0 |

### 14.7.2.5—Coefficient of Friction

The service limit design coefficient of friction of the PTFE sliding surface shall be taken as specified in Table 14.7.2.5-1. Intermediate values may be determined by interpolation. The coefficient of friction shall be determined by using the stress level associated with the applicable load combination specified in Table 3.4.1-1. Lesser values may be used if verified by tests.

Where friction is required to resist nonseismic loads, the design coefficient of friction under dynamic loading may be taken as not more than ten percent of the values listed in Table 14.7.2.5-1 for the bearing stress and PTFE type indicated.

The coefficients of friction in Table 14.7.2.5-1 are based on a 8.0 μ-in. finish mating surface. Coefficients of friction for rougher surface finishes must be established by test results in accordance with the *AASHTO LRFD Bridge Construction Specifications*, Chapter 18.

The contract documents shall require certification testing from the production lot of PTFE to ensure that the friction actually achieved in the bearing is appropriate for the bearing design.

### C14.7.2.5

The friction factor decreases with lubrication and increasing contact stress but increases with sliding velocity (Campbell and Kong, 1987). The coefficient of friction also tends to increase at low temperatures. Static friction is larger than dynamic friction, and the dynamic coefficient of friction is larger for the first cycle of movement than it is for later cycles. Friction increases with increasing roughness of the mating surface and decreasing temperature. The friction factors used in the 17th edition of the AASHTO *Standard Specifications for Highway Bridges* are suitable for use with dimpled, lubricated PTFE. They are too small for the flat, dry PTFE commonly used in the United States. These Specifications have been changed to recognize this fact. Nearly all research to date has been performed on dimpled, lubricated PTFE. The coefficients of friction given in Table 14.7.2.5-1 are not applicable to high-velocity movements such as those occurring in seismic events. Seismic velocity coefficients of friction must be determined in accordance with the AASHTO *Guide Specifications for Seismic Isolation Design*. Coefficients of friction somewhat smaller than those given in Table 14.7.2.5-1 are possible with care and quality control.

Certification testing from the production lot is essential for PTFE sliding surfaces primarily to ensure that the friction actually achieved in the bearing is appropriate for the bearing design. Testing is the only reliable method for certifying the coefficient of friction and bearing behavior.

Contamination of the sliding surface with dirt and dust increases the coefficient of friction and increases the wear of the PTFE. To prevent contamination, the bearing should be sealed by the manufacturer and not separated at the construction site. To prevent contamination and gouging of the PTFE, the stainless steel should normally be on top and should be larger than the PTFE, plus its maximum travel.

Woven PTFE is sometimes formed by weaving pure PTFE strands with a reinforcing material. These reinforcing strands may increase the resistance to creep and cold flow and can be woven so that reinforcing strands do not appear on the sliding surface. This separation is necessary if the coefficients of friction provided in Table 14.7.2.5-1 are to be used.

If there is no lubricant in the dimples, the dimples tend to flatten out, filling the dimples and resulting in a surface much like unfilled PTFE.

| | −13 | 0.20 | 0.180 | 0.130 | 0.100 |
| | −49 | 0.20 | 0.180 | 0.130 | 0.100 |

### 14.7.2.6—Attachment

*14.7.2.6.1—PTFE*

Sheet PTFE confined in a recess in a rigid metal backing plate for one-half its thickness may be bonded or unbonded.

Sheet PTFE that is not confined shall be bonded to a metal surface or an elastomeric layer with a Shore A durometer hardness of at least 90 by an approved method.

Woven PTFE on a metallic substrate shall be attached to the metallic substrate by mechanical interlocking that can resist a shear force no less than 0.10 times the applied compressive force.

*C14.7.2.6.1*

Recessing is the most effective way of preventing creep in unfilled PTFE. The PTFE discs may also be bonded into the recess, but this is optional and the benefits are debatable. Bonding helps to retain the PTFE in the recess during the service life of the bridge, but it makes replacement of the disc more difficult. If the adhesive is not applied uniformly it can cause an uneven PTFE sliding surface that could lead to premature wear. Some manufacturers cut the PTFE slightly oversize and pre-cool it before installation because this results in a tighter fit at room temperature.

Sometimes PTFE is bonded to the top cover layer of an elastomeric bearing. This layer should be relatively thick and hard to avoid rippling of the PTFE (Roeder et al., 1987). PTFE must be etched prior to epoxy bonding in order to obtain good adhesion. However, ultra-violet light attacks the etching and can lead to delamination, so PTFE exposed to ultra-violet light should not be attached by bonding alone.

*14.7.2.6.2—Mating Surface*

The mating surface for flat sliding surfaces shall be attached to a backing plate by welding in such a way that it remains flat and in full contact with its backing plate throughout its service life. The weld shall be detailed to form an effective moisture seal around the entire perimeter of the mating surface to prevent interface corrosion. The attachment shall be capable of resisting the maximum friction force that can be developed by the bearing under service limit state load combinations. The welds used for the attachment shall be clear of the contact and sliding area of the PTFE surface.

*C14.7.2.6.2*

The restrictions on the attachment of the mating surface are primarily intended to ensure that the surface is flat and retains uniform contact with the PTFE at all times, without adversely affecting the friction of the surface or gouging or cutting the PTFE.

The mating surface of curved sliding surfaces should be machined to the required surface finish from a single piece.

## 14.7.3—Bearings with Curved Sliding Surfaces

### 14.7.3.1—General

Bearings with curved sliding surfaces shall consist of two metal parts with matching curved surfaces and a low-friction sliding interface. The curved surfaces may be either cylindrical or spherical. The material properties, characteristics, and frictional properties of the sliding interface shall satisfy the requirements specified in Articles 14.7.2 and 14.7.7.

The two surfaces of a sliding interface shall have equal nominal radii.

### C14.7.3.1

These provisions are directed primarily toward spherical or cylindrical bearings with bronze or PTFE sliding surfaces.

Some jurisdictions require that the minimum center thickness of concave spherical surfaces be at least 0.75 in. and that a minimum vertical clearance between the rotating and nonrotating parts be as given by Eqs. C14.7.3.1-1 or C14.7.3.1-2 but not less than 0.125 in.

- For rectangular spherical or curved bearings:

$$c = 0.7D\theta_u + 0.125 \qquad \text{(C14.7.3.1-1)}$$

- For round spherical or round bearings:

$$c = 0.5D\theta_u + 0.125 \qquad \text{(C14.7.3.1-2)}$$

where:

$\theta_u$ = design rotation from applicable strength load combinations in Table 3.4.1-1 or Article 14.4.2.2.1 (rad.)

Similarly, the minimum edge thickness on the convex surface has sometimes been limited to 0.75 in. for bearing on concrete and 0.50 in. for bearing on steel.

### 14.7.3.2—Bearing Resistance

The radius of the curved surface shall be large enough to ensure that the total compressive load at the service limit state on the horizontal projected area of the bearing, $P_s$, is less than or equal to the average allowable load as computed from the service stress specified in Articles 14.7.2.4 or 14.7.7.3.

- For cylindrical bearings:

$$P_s \le \phi DW\sigma_{SS} \qquad \text{(14.7.3.2-1)}$$

- For spherical bearings:

$$P_s \le \phi \frac{\pi D^2 \sigma_{SS}}{4} \qquad \text{(14.7.3.2-2)}$$

where:

$P_s$ = total compressive load from applicable service load combinations in Table 3.4.1-1 (kip)

$D$ = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.)

$\sigma_{SS}$ = maximum average contact stress at the service limit state permitted on PTFE by

### C14.7.3.2

The geometry of a spherical bearing controls its ability to resist lateral loads, its moment-rotation behavior, and its frictional characteristics. The geometry is relatively easy to define, but it has some consequences that are not widely appreciated. The stress may vary over the contact surface of spherical or cylindrical bearings. Cylindrical and spherical surfaces cannot be machined as accurately as a flat smooth surface. It is important that the radius of the convex and concave surfaces be within appropriate limits. If these limits are exceeded the bronze may crack due to hard bearing contact, or there may be excessive wear and damage due to creep or cold flow of the PTFE. The stress limits used in this Section are based on average contact stress levels.

Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi)
$W$ = length of cylinder (in.)
$\phi$ = resistance factor taken as 1.0

### 14.7.3.3—Resistance to Lateral Load

Where bearings are required to resist horizontal loads at the service limit state, an external restraint system shall be provided or:

- For a cylindrical sliding surface, the horizontal load shall satisfy:

$$H_s \le 2RW\sigma_{SS}\sin(\psi-\beta-\theta_u)\sin\beta \quad (14.7.3.3\text{-}1)$$

- For a spherical surface, the horizontal load shall satisfy:

$$H_s \le \pi R^2\sigma_{SS}\sin(\psi-\beta-\theta_u)\sin\beta \quad (14.7.3.3\text{-}2)$$

in which:

$$\beta = \tan^{-1}\left(\frac{H_s}{P_D}\right) \quad (14.7.3.3\text{-}3)$$

and

$$\psi = \sin^{-1}\left(\frac{L}{2R}\right) \quad (14.7.3.3\text{-}4)$$

where:

$H_s$ = horizontal load from applicable service load combinations in Table 3.4.1-1 (kip)
$L$ = projected length of the sliding surface perpendicular to the rotation axis (in.)
$P_D$ = compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip)
$R$ = radius of curved sliding surface (in.)
$W$ = length of cylindrical surface (in.)
$\beta$ = angle between the vertical and resultant applied load (rad.)
$\theta_u$ = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)
$\sigma_{SS}$ = maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1 or on bronze by Table 14.7.7.3-1 (ksi)
$\Psi$ = subtended semiangle of the curved surface (rad.)

### C14.7.3.3

The geometry of a curved bearing combined with gravity loads can provide considerable resistance to lateral load. An external restraint is often a more reliable method of resisting large lateral loads at the service and strength limit states, and at the extreme event limit state when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The applied loads for determination of the angle $\beta$ and the applied load check are at the service limit state because the stress limits, $\sigma_{ss}$, are service-based. The rotation at the strength limit state is utilized because bearings with curved sliding surfaces are susceptible to more serious consequences if overloaded or over rotated.

The geometry of a cylindrical sliding bearing is shown in the deformed position in Figure C14.7.3.3-1.

## 14.7.4—Pot Bearings

### 14.7.4.1—General

Where pot bearings are provided with a PTFE slider to provide for both rotation and horizontal movement, such sliding surfaces and any guide systems shall be designed in accordance with the provisions of Articles 14.7.2 and 14.7.9.

The rotational elements of the pot bearing shall consist of at least a pot, a piston, an elastomeric disc, and sealing rings.

For the purpose of establishing the forces and deformations imposed on a pot bearing, the axis of rotation shall be taken as lying in the horizontal plane at midheight of the elastomeric disc.

The minimum vertical load on a pot bearing should not be less than 20 percent of the vertical design load.

### 14.7.4.2—Materials

The elastomeric disc shall be made from a compound based on virgin natural rubber or virgin neoprene conforming to the requirements of Section 18.3 of the AASHTO *LRFD Bridge Construction Specifications*. The nominal hardness shall lie between 50 and 60 on the Shore A scale.

The pot and piston shall be made from structural steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709), Grades 36, 50, or 50W; or from stainless steel conforming to ASTM A240. The finish of surfaces in contact with the elastomeric pad shall be smoother than 60 μ-in. The yield strength and hardness of the piston shall not exceed that of the pot.

Brass sealing rings satisfying Articles 14.7.4.5.2 and 14.7.4.5.3 shall conform to ASTM B36 (half hard) for rings of rectangular cross-section, and Federal Specification QQB626, Composition 2, for rings of circular cross-section.

### 14.7.4.3—Geometric Requirements

The depth of the elastomeric disc, $h_r$, shall satisfy:

$$h_r \geq 3.33 D_p \theta_u \qquad (14.7.4.3\text{-}1)$$

where:

$D_p$ = internal diameter of pot (in.)
$\theta_u$ = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

The dimensions of the elements of a pot bearing shall satisfy the following requirements under the least favorable combination of strength limit state displacements and rotations:

- the pot shall be deep enough to permit the seal and piston rim to remain in full contact with the vertical face of the pot wall, and

### C14.7.4.2

Softer elastomers permit rotation more readily and are preferred.

Corrosion-resistant steels, such as AASHTO M 270M/M 270 (ASTM A709/A709), Grade 50W, are not recommended for applications where they may come into contact with saltwater or be permanently damp, unless their whole surface is completely corrosion protected. Most pot bearings are machined from a solid plate, so use of high-strength steel to decrease the wall thickness results in only a very small reduction in volume of material used.

Other properties, such as corrosion resistance, ease of machining, electrochemical compatibility with steel girders, availability, and price should also be considered. The provision on relative hardness is mentioned to avoid wear or damage on the inside surface of the pot and the consequent risk of seal failure.

The choice of brass for sealing rings reflects present practice.

### C14.7.4.3

The requirements of this Article are intended to prevent the seal from escaping and the bearing from locking up even under the most adverse conditions. Use of the design rotation, $\theta_u$, means that the designer should account for both the anticipated movements due to loads and those due to fabrication and installation tolerances, including the rotation imposed on the bearing due to out-of-level of other bridge components, such as undersides of prefabricated girders, and permissible misalignments during construction. Vertical deflection caused by compressive load should also be taken into account because it will reduce the available clearance. Anchor bolts projecting above the base plate should be taken into consideration when clearance is determined.

Rotation capacity can be increased by using a deeper pot, a thicker elastomeric pad, and a larger vertical clearance between the pot wall and the piston or slider. The

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

- contact or binding between metal components shall not prevent further displacement or rotation.

minimum thickness of the pad specified herein results in edge deflections due to rotation no greater than 15 percent of the nominal pad thickness. Figure C14.7.4.3-1 and Eqs. C14.7.4.3-1 and C14.7.4.3-2 may be used to verify clearance.

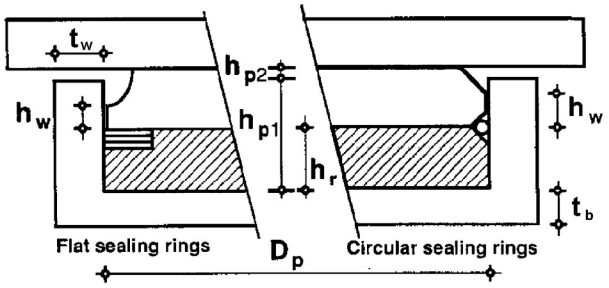

**Figure C14.7.4.3-1—Pot Bearing—Critical Dimensions for Clearances**

The pot cavity depth, $h_{p1}$, may be determined as:

$$h_{p1} \geq \left(0.5 D_p \theta_u\right) + h_r + h_w \qquad \text{(C14.7.4.3-1)}$$

where:

$h_r$ = depth of elastomeric disc (in.)
$h_w$ = height from top of rim to underside of piston (in.)

The vertical clearance between top of piston and top of pot wall, $h_{p2}$, may be determined as:

$$h_{p2} \geq R_o \theta_u + 2\delta_u + 0.125 \qquad \text{(C14.7.4.3-2)}$$

where:

$\delta_u$ = vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.)
$R_o$ = radial distance from center of pot to object in question (e.g., pot wall, anchor bolt, etc.) (in.)

Note that Eq. C14.7.4.3-1 does not contain any allowance for vertical deflection, $\delta_u$. This omission is conservative. The design rotation, $\theta_u$, already represents an extreme rotation for use with the strength limit state and requires no further factoring.

$\delta_u$ and $\theta_u$ may also be considered at the extreme event limit state.

Thicker pads with deeper pots cause smaller strains in the elastomer, and they appear to experience less wear and abrasion. Recessing of the rings into the pad is necessary for satisfactory pad performance, but it also decreases the effective thickness of the pad at that location. Further, the recess has sometimes been cut into the pad, and this cut appears to make the pad susceptible to additional damage. Therefore, it is generally better to use a deeper pot and thicker pad even though this leads to greater material and machining costs.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 14.7.4.4—Elastomeric Disc

The average stress on the elastomer at the service limit state should not exceed 3.5 ksi.

To facilitate rotation, the top and bottom surfaces of the elastomer shall be treated with a lubricant that is not detrimental to the elastomer. Alternatively, thin PTFE discs may be used on the top and bottom of the elastomer.

### C14.7.4.4

The average stress on the elastomeric disc is largely limited by the seal's ability to prevent escape of the elastomer. The 3.5 ksi level has been used as a practical upper limit for some years, and most bearings have performed satisfactorily but a few seal failures have occurred. The experimental research of NCHRP 10-20A showed that greater wear and abrasion due to cyclic rotation occurred when higher stress levels are employed, but this correlation is not strong. As a result, the 3.5 ksi stress limit is retained as a practical design limit.

Lubrication helps prevent abrasion of the elastomer during cyclic rotation; however, research has shown that the beneficial effect of the lubrication tends to be lost with time. Silicon grease has been used with success. It performed well in experiments and is recommended. Thin sheets of PTFE have also been used. These sheets performed quite well in experimental studies, but they are less highly recommended because there is a concern that they may wrinkle and become ineffective. Powdered graphite has been used but has not performed well in rotation experiments. As a result, silicon grease is the preferred lubricant, and powdered graphite is not recommended. PTFE discs are permitted as a method of lubrication, but the user should be aware that some problems have been reported.

### 14.7.4.5—Sealing Rings

#### *14.7.4.5.1—General*

A seal shall be used between the pot and the piston. At the service limit state, seals shall be adequate to prevent escape of elastomer under compressive load and simultaneously applied cyclic rotations. At the strength limit state, seals shall also be adequate to prevent escape of elastomer under compressive load and simultaneously applied static rotation.

Brass rings satisfying the requirements of either Article 14.7.4.5.2 or 14.7.4.5.3 may be used without testing to satisfy the above requirements. The Engineer may approve other sealing systems on the basis of experimental evidence.

#### *C14.7.4.5.1*

Failure of seals has been one of the most common problems in pot bearings. Multiple flat brass rings, circular brass rod formed and brazed into a ring, and proprietary plastic rings have been found to be successful. Experimental research suggests that solid circular brass rings provide a tight fit and prevent leakage of the elastomer, but they experience severe wear during cyclic rotation. Experiments suggest that flat brass rings are somewhat more susceptible to elastomer leakage and fracture, but they are less prone to wear. PTFE rings should not be used. The rings should preferably be recessed into the elastomer or vulcanized to it in order to minimize distortion of the elastomer.

Cyclic rotation of the bearing due to temperature variations or traffic loading can cause chafing of the elastomer against the pot wall, which can give rise to some loss of elastomer past the seal. The detail design of the sealing system is important in preventing this. The details of the tests for alternative sealing systems are left to the discretion of the Engineer. However, tests should include cyclic rotation.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*14.7.4.5.2—Rings with Rectangular Cross-Sections*

Three rectangular rings shall be used. Each ring shall be circular in plan but shall be cut at one point around its circumference. The faces of the cut shall be on a plane at 45 degrees to the vertical and to the tangent of the circumference. The rings shall be oriented so that the cuts on each of the three rings are equally spaced around the circumference of the pot.

The width of each ring shall not be less than either 0.02 $D_p$ or 0.25 in. and shall not exceed 0.75 in. The depth of each shall not be less than 0.2 times its width.

*14.7.4.5.3—Rings with Circular Cross-Sections*

One circular closed ring shall be used with an outside diameter of $D_p$. It shall have a cross-sectional diameter not less than either 0.0175 $D_p$ or 0.15625 in.

**14.7.4.6—Pot**

The pot shall consist at least of a wall and base. All elements of the pot shall be designed to act as a single structural unit.

The minimum thickness of a base bearing directly against concrete or grout shall satisfy:

- $t_b \geq 0.06 D_p$ and (14.7.4.6-1)
- $t_b \geq 0.75\,\text{in.}$ (14.7.4.6-2)

The thickness of a base bearing directly on steel girders or load distribution plates shall satisfy:

- $t_b \geq 0.04 D_p$ and (14.7.4.6-3)
- $t_b \geq 0.50\,\text{in.}$ (14.7.4.6-4)

The minimum pot wall thickness, $t_w$, for an unguided sliding pot bearing shall satisfy:

$$t_w \geq \frac{D_p \sigma_s}{1.25 F_y} \quad (14.7.4.6\text{-}5)$$

and:

$$t_w \geq 0.75\,\text{in.} \quad (14.7.4.6\text{-}6)$$

where:

$t_w$ = pot wall thickness (in.)
$F_y$ = yield strength of the steel (ksi)
$D_p$ = internal diameter of pot (in.)
$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

**C14.7.4.6**

Pots are constructed most reliably by machining from a single plate. For very large bearings, this may become prohibitively expensive, so fabrication by welding a ring to a base plate is implicitly accepted. However, the ring must be attached to the plate by a full penetration weld because the wall is subject to significant bending moments where it joins the base plate. The quality of welding should be assured by quality control. The finished inside profile of the pot must satisfy the required shape and tolerances. Straightening and machining may be needed to rectify welding distortions.

The lower bounds on the thickness of the base plate are intended to provide some rigidity to counteract the effects of uneven bearing. If the base plate was to deform significantly, the volume of elastomer would be inadequate to fill the space in the pot, and hard contact could occur between some elements.

Eqs. 14.7.4.6-5 and 14.7.4.6-6 define minimum wall thickness requirements for unguided pot bearings. Eq. 14.7.4.6-5 is based upon hoop strength of the pot walls with the elastomeric disc under hydrostatic compressive stress. This equation is conservative for this application, because it neglects the beneficial effect of the bending strength and stiffness at the pot wall–base interface. However, this equation provides no lateral (horizontal) resistance to the bearing, and it is limited to unguided bearings (Stanton, 1999).

The limitation of Eq. 14.7.4.6-6 is based upon past manufacturing practice (SCEF, 1991).

The surface finish on the inside of the pot may have considerable impact on bearing performance. A smooth finish reduces rotational resistance and wear and abrasion of the elastomer. It may also improve the performance of the sealing rings, but at present there are no definitive limits as to what the surface finish should ideally be for

The wall thickness, $t_w$, and base thickness, $t_b$, of guided or fixed pots shall also satisfy the requirements of Eq. 14.7.4.7-1 for applicable strength and extreme event load combinations specified in Table 3.4.1-1 which are transferred by the piston to the pot wall.

**14.7.4.7—Piston**

The piston shall have the same plan shape as the inside of the pot. Its thickness shall be adequate to resist the loads imposed on it, but shall not be less than six percent of the inside diameter of the pot, $D_p$, except at the rim.

The perimeter of the piston shall have a contact rim through which horizontal loads may be transmitted. In circular pots, its surface may be either cylindrical or spherical. The body of the piston above the rim shall be set back or tapered to prevent binding. The height, $w$, of the piston rim shall be large enough to transmit the strength and extreme event limit states' horizontal forces between the pot and the piston.

Where a mechanical device is used to connect the superstructure to the substructure, it shall be designed to resist the greater of $H_u$ at the support for the strength and extreme event limit states, or 15 percent of the maximum vertical load at the service limit state at that location.

Pot bearings subjected to lateral loads shall be proportioned so that the thickness of the pot wall, $t_w$, and the pot base, $t_b$, shall satisfy:

$$t_w, t_b \geq \sqrt{\frac{25 H_u \theta_u}{F_y}} \qquad (14.7.4.7\text{-}1)$$

Pot bearings that transfer load through the piston shall satisfy:

$$h_w \geq \frac{1.5 H_u}{D_p F_y} \qquad (14.7.4.7\text{-}2)$$

$$h_w \geq 0.125 \text{ in., and} \qquad (14.7.4.7\text{-}3)$$

$$h_w \geq 0.03 D_p \qquad (14.7.4.7\text{-}4)$$

where:

$H_u$ = lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)
$\theta_u$ = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)
$F_y$ = yield strength of steel (ksi)
$D_p$ = internal diameter of pot (in.)
$h_w$ = height from top of rim to underside of piston (in.)

good bearing performance. Metalization on the inside of the pot tends to cause a rougher surface finish, which leads to significant increases in damage under cyclic rotation; as a result, metalization may not be a good method of protection.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

**C14.7.4.7**

The required piston thickness is controlled by rigidity and strength. A central internal guide bar fitted in a slot in the piston causes bending moments that are largest where the piston is weakest. In this case, the piston must also be thick enough to supply an adequate grip length for any bolts used to secure the guide bar.

If the piston rotates while a horizontal load is acting, the piston rim will be subject to bearing stresses due to horizontal load and to shear forces. If the rim surface is cylindrical, contact between it and the pot wall will theoretically be along a line when the piston rotates. In practice, some localized yielding is inevitable. If the rim surface forms part of a sphere, the contact area will be finite, providing less potential for local damage. Damage to the pot wall should be avoided because it will jeopardize the effectiveness of the seal. The dimensions of the rim depend on the contact area, and because this is uncertain, the rim should be designed conservatively. Eq. 14.7.4.7-4 is based on consideration of bearing stresses alone, using a strength limit state horizontal force of 0.15 times the vertical service limit state load, $F_y$ = 50.0 ksi and $\phi$ = 0.9.

The 15 percent factor applied to the service limit state vertical load, embedded in Eq. 14.7.4.7-4 and used in the design of mechanical devices that connect the superstructure to the substructure, approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted. $\theta_u$ may also be considered at the extreme event limit state.

The clearance between piston and pot is critical to the proper functioning of the bearing. In most bearings the finished clearance, after anticorrosion coatings have been applied, should be about 0.02 to 0.04 in., a range that is easily achievable. The equation for minimum clearance is based on geometry. Eq. 14.7.4.7-5 may occasionally produce a negative number; however, in these instances the minimum value of 0.02 in. controls.

$$S_i = \frac{LW}{2h_{ri}(L+W)} \quad (14.7.5.1\text{-}1)$$

where:

$L$ = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
$W$ = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
$h_{ri}$ = thickness of $i$th elastomeric layer (in.)

For circular bearings without holes, the shape factor of a layer may be taken as:

$$S_i = \frac{D}{4h_{ri}} \quad (14.7.5.1\text{-}2)$$

where:

$D$ = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.)

the loaded area and increase the area free to bulge. Suitable shape factor formulae are:

- For rectangular bearings:

$$S_i = \frac{LW - \Sigma\frac{\pi}{4}d^2}{h_{ri}[2L + 2W + \Sigma\pi d]} \quad (C14.7.5.1\text{-}1)$$

- For circular bearings:

$$S_i = \frac{D^2 - \Sigma d^2}{4h_{ri}(D + \Sigma d)} \quad (C14.7.5.1\text{-}2)$$

where:

$d$ = the diameter of the hole or holes in the bearing (in.)

Large steel-reinforced elastomeric bearings (defined as those which are thicker than 8 in. or having a plan area greater than 1,000 in.$^2$) are more difficult to fabricate than small ones. The consequences of failure are also likely to be more severe in a large bearing. As such, large bearings should be designed according to Method B, which requires additional testing and quality control.

**14.7.5.2—Material Properties**

The shear modulus of the elastomer at 73°F shall be used as the basis for design.

The elastomer shall have a specified shear modulus between 0.080 and 0.175 ksi. It shall conform to the requirements of Section 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251.

The acceptance criteria in AASHTO M 251 shall be followed which:

- permits a variation of ±15 percent from the value specified for shear modulus according to the first and second paragraphs of this Article, and
- does not permit a shear modulus below 0.080 ksi.

For design purposes, the shear modulus shall be taken as the least favorable of the values in the ranges described above.

**C14.7.5.2**

Shear modulus, $G$, is the most important material property for design, and it is, therefore, the primary means of specifying the elastomer. Hardness has been widely used in the past, and is still permitted for Method A design, because the test for it is quick and simple. However, the results obtained from it are variable and correlate only loosely with shear modulus.

Materials with a specified shear modulus greater than 0.175 ksi are prohibited because they generally have a smaller elongation at break and greater stiffness and greater creep than their softer counterparts. This inferior performance is generally attributed to the larger amounts of filler present. Their fatigue behavior does not differ in a clearly discernible way from that of softer materials.

The least favorable value for the shear modulus used in design calculations is dependent upon whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. The forgiving nature of elastomers tends to compensate for service and installation conditions which are less than ideal. (See

All rights reserved. Duplication is a violation of applicable law.

Other properties, such as creep deflection, should be obtained from Table 14.7.6.2-1 or from tests conducted using AASHTO M 251.

For the purposes of bearing design, all bridge sites shall be classified as being in temperature Zones A, B, C, D, or E for which design data are given in Table 14.7.5.2-1. In the absence of more precise information, Figure 14.7.5.2-1 may be used as a guide in selecting the zone required for a given region.

Bearings shall be made from AASHTO low-temperature grades of elastomer as defined in Section 18 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251. The minimum grade of elastomer required for each low-temperature zone shall be taken as specified in Table 14.7.5.2-1.

Any of the three design options listed below may be used:

- Specify the elastomer with the minimum low-temperature grade indicated in Table 14.7.5.2-1 and determine the shear force transmitted by the bearing as specified in Article 14.6.3.1;
- Specify the elastomer with the minimum low-temperature grade for use when special force provisions are incorporated in the design and provide a low-friction sliding surface, in which case the bridge shall be designed to withstand twice the design shear force specified in Article 14.6.3.1; or
- Specify the elastomer with the minimum low- temperature grade for use when special force provisions are incorporated in the design but do not provide a low-friction sliding surface, in which case the components of the bridge shall be designed to resist four times the design shear force as specified in Article 14.6.3.1.

Article 14.7.5.3.2.) Despite this, the designer should be cautious about specifying a shear modulus which is at or near the specified upper or lower bounds of 0.175 ksi and 0.080 ksi, respectively.

The zones are defined by their extreme low temperatures or the largest number of consecutive days when the temperature does not rise above 32°F, whichever gives the more severe condition.

Shear modulus increases as the elastomer cools, but the extent of stiffening depends on the elastomer compound, time, and temperature. It is, therefore, important to specify a material with low-temperature properties that are appropriate for the bridge site. In order of preference, the low-temperature classification should be based on:

- the 50-year temperature history at the site,
- a statistical analysis of a shorter temperature history, or
- Figure 14.7.5.2-1.

Table 14.7.5.2-1 gives the minimum elastomer grade to be used in each zone. A grade suitable for a lower temperature may be specified by the Engineer, but improvements in low-temperature performance can often be obtained only at the cost of reductions in other properties. This low-temperature classification is intended to limit the force on the bridge substructure to 1.5 times the service limit state design force under extreme environmental conditions.

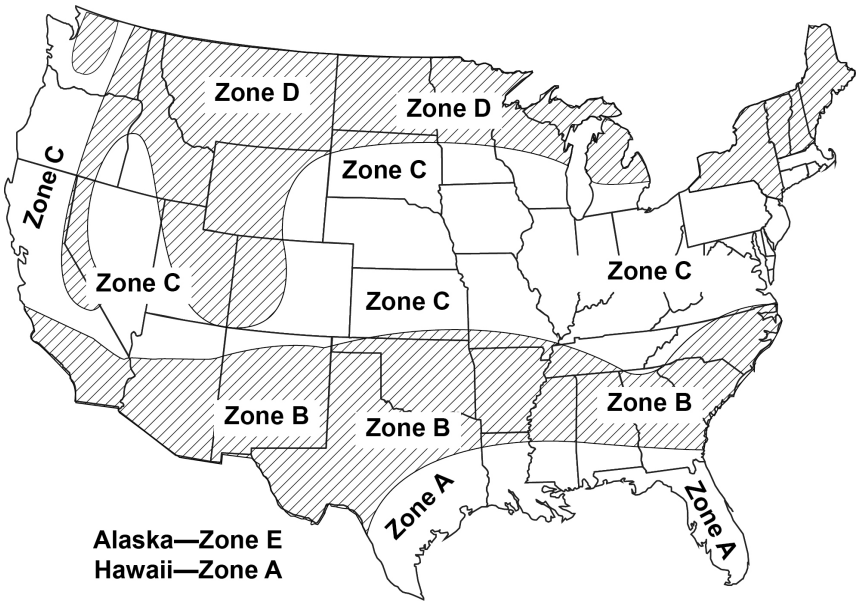

**Figure 14.7.5.2-1—Temperature Zones**

**Table 14.7.5.2-1—Low-temperature Zones and Minimum Grades of Elastomer**

| Low-temperature Zone | A | B | C | D | E |
|---|---|---|---|---|---|
| 50-year low temperature (°F) | 0 | −20 | −30 | −45 | <−45 |
| Maximum number of consecutive days when the temperature does not rise above 32°F | 3 | 7 | 14 | N/A | N/A |
| Minimum low-temperature elastomer grade | 0 | 2 | 3 | 4 | 5 |
| Minimum low-temperature elastomer grade when special force provisions are incorporated | 0 | 0 | 2 | 3 | 5 |

### 14.7.5.3—Design Requirements

*14.7.5.3.1—Scope*

Bearings designed by the provisions herein shall be tested in accordance with the requirements for steel-reinforced elastomeric bearings as specified in Article 18.2 of the AASHTO *LRFD Bridge Construction Specifications* and the AASHTO M 251.

*C14.7.5.3.1*

Steel-reinforced bearings are designed to resist relatively high stresses. Their integrity depends on good quality control during manufacture, which can only be ensured by rigorous testing.

*14.7.5.3.2—Shear Deformations*

The maximum horizontal displacement of the bridge superstructure, $\Delta_O$, shall be taken as 65 percent of the design thermal movement range, $\Delta_T$, computed in accordance with Article 3.12.2, combined with movements caused by creep, shrinkage, and post-tensioning.

The maximum shear deformation of the bearing at the service limit state, $\Delta_S$, shall be taken as $\Delta_O$, modified to account for the substructure stiffness and construction procedures. If a low-friction sliding surface is installed, $\Delta_S$ need not be taken to be larger than the deformation corresponding to first slip.

*C14.7.5.3.2*

The shear deformation is limited to $\pm 0.5\ h_{rt}$ in order to avoid rollover at the edges and delamination due to fatigue.

Generally, the installation temperature is within ±15 percent of the average of the maximum and minimum design temperatures. Consequently, 65 percent of the thermal movement range is used for design purposes (Roeder, 2002). The forgiving nature of elastomeric bearings more than accounts for actual installation temperatures greater than or less than the likely approximated installation temperature. Additionally, if the bearing is originally set or reset at the average of the design temperature range, 50 percent of the design thermal movement range computed

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The bearing shall satisfy:

$$h_{rt} \geq 2\Delta_S \qquad (14.7.5.3.2\text{-}1)$$

where:

$h_{rt}$ = total elastomer thickness (in.)
$\Delta_S$ = maximum total shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.)

in accordance with Article 3.12.2 may be substituted for 65 percent as specified.

Fatigue tests that formed the basis for this provision were conducted to 20,000 cycles, which represents one expansion/contraction cycle per day for approximately 55 years (Roeder et al., 1990). The provisions will, therefore, be unconservative if the shear deformation is caused by high-cycle loading due to braking forces or vibration. The maximum shear deformation due to these high-cycle loadings should be restricted to no more than $\pm 0.10\ h_{rt}$, unless better information is available. At this strain amplitude, the experiments showed that the bearing has an essentially infinite fatigue life.

If the bridge girders are lifted to allow the bearings to realign after some of the girder shortening has occurred, that may be accounted for in design.

Pier deflections sometimes accommodate a significant portion of the bridge movement, and this may reduce the movement that must be accommodated by the bearing. Construction methods may increase the bearing movement because of poor installation tolerances or poor timing of the bearing installation.

*14.7.5.3.3—Combined Compression, Rotation, and Shear*

Combinations of axial load, rotation, and shear at the service limit state shall satisfy:

$$\left(\gamma_{a,st} + \gamma_{r,st} + \gamma_{s,st}\right) + 1.75\left(\gamma_{a,cy} + \gamma_{r,cy} + \gamma_{s,cy}\right) \leq 5.0 \qquad (14.7.5.3.3\text{-}1)$$

The static component of $\gamma_a$ shall also satisfy:

$$\gamma_{a,st} \leq 3.0 \qquad (14.7.5.3.3\text{-}2)$$

where:

$\gamma_a$ = shear strain caused by axial load
$\gamma_r$ = shear strain caused by rotation
$\gamma_s$ = shear strain caused by shear displacement

Subscripts "*st*" and "*cy*" indicate static and cyclic loading, respectively. Cyclic loading shall consist of loads induced by traffic. All other loads may be considered static. In rectangular bearings, the shear strains shall be evaluated for rotation about the axis which is parallel to the transverse axis of the bridge. Evaluation of shear strains for rotation about the axis which is parallel to the longitudinal axis of the bridge should also be considered. For circular bearings, the rotations about two primary orthogonal axes shall be added vectorially, and the shear strains shall be evaluated using the largest sum.

*C14.7.5.3.3*

Elastomers are almost incompressible, so when a steel-laminated bearing is loaded in compression, the elastomer expands laterally due to the Poisson effect. That expansion is partially restrained by the steel plates to which the elastomer layers are bonded, and the restraint results in bulging of the layers between the plates. The bulging creates shear stresses at the bonded interface between the elastomer and steel. If they become large enough, they can cause shear failure of the bond or the elastomer adjacent to it. This is the most common form of damage in steel-laminated elastomeric bearings and is the reason why limitations on the shear strain in the elastomer dominate the design requirements.

The cyclic components of the loading are multiplied by an amplification factor of 1.75 in Eq. 14.7.5.3.3-1. This reflects the results of tests that showed that cyclic shear strain causes more debonding damage than a static shear strain of the same amplitude. This approach of using an explicit summation of the shear strain components coupled with an amplification factor on cyclic components is found in other specifications, such as the European EN 1337.

In some cases, the rotations due to dead and live load will have opposite signs, in which case use of the amplification factor of 1.75 could lead to an amplified rotation that is artificially low. This is clearly not consistent with the intent of the amplification factor. In cases where the sense of the loading components in

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The shear strains $\gamma_a$, $\gamma_r$, and $\gamma_s$, shall be established by rational analysis, in lieu of which the following approximations are acceptable.

The shear strain due to axial load may be taken as:

$$\gamma_a = D_a \frac{\sigma_s}{GS_i} \tag{14.7.5.3.3-3}$$

in which, for a rectangular bearing:

$$D_a = 1.4 \tag{14.7.5.3.3-4}$$

and, for a circular bearing:

$$D_a = 1.0 \tag{14.7.5.3.3-5}$$

where:

$D_a$ = dimensionless coefficient used to determine shear strain due to axial load
$G$ = shear modulus of the elastomer (ksi)
$S_i$ = shape factor of the $i$th internal layer of an elastomeric bearing
$\sigma_s$ = average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi)

The shear strain due to rotation for a rectangular bearing may be taken as:

$$\gamma_r = D_r \left(\frac{L}{h_{ri}}\right)^2 \frac{\theta_s}{n} \tag{14.7.5.3.3-6}$$

in which:

$$D_r = 0.5 \tag{14.7.5.3.3-7}$$

and, for a circular bearing:

$$\gamma_r = D_r \left(\frac{D}{h_{ri}}\right)^2 \frac{\theta_s}{n} \tag{14.7.5.3.3-8}$$

in which:

$$D_r = 0.375 \tag{14.7.5.3.3-9}$$

where:

$D$ = diameter of the bearing (in.)
$D_r$ = dimensionless coefficient used to determine shear strain due to rotation
$h_{ri}$ = thickness of $i$th internal elastomeric layer (in.)
$L$ = plan dimension of the bearing perpendicular to the critical combination is unclear, the sum of the absolute value should be used.

For rectangular bearings, separate evaluations about each primary rotation axis (parallel to the transverse global axis and parallel to the longitudinal global axis of the bridge) may be necessary and appropriate, such as for structures with significant skew. Where rectangular bearings are evaluated about an axis parallel to the global longitudinal axis of the bridge, the definitions of $L$ and $W$ should be interchanged.

For highly skewed or curved bridges, the girder ends will significantly rotate in both bending and torsion. Circular bearings offer a good alternative.

The constants 1.4 assigned to $D_a$ and 0.5 assigned to $D_r$ for rectangular bearings represent simplified values for determining shear strains which are evaluated for rotation about an axis which is parallel to the transverse axis of the bridge. They were derived from procedures suggested by Stanton et al. (2007). $D_a$ and $D_r$ may alternatively be determined with Eqs. C14.7.5.3.3-1 through C14.7.5.3.3-6 about either primary orthogonal axis for rectangular bearings.

$$D_a = \max\left[d_{a1}, \left(d_{a2} + d_{a3} \times \frac{L}{W}\right)\right] \tag{C14.7.5.3.3-1}$$

$$D_r = \frac{1.552 - 0.627\lambda}{2.233 + 0.156\lambda + \frac{L}{W}} \le 0.5 \tag{C14.7.5.3.3-2}$$

in which:

$$d_{a1} = 1.06 + 0.210\lambda + 0.413\lambda^2 \tag{C14.7.5.3.3-3}$$

$$d_{a2} = 1.506 - 0.071\lambda + 0.406\lambda^2 \tag{C14.7.5.3.3-4}$$

$$d_{a3} = -0.315 + 0.195\lambda - 0.047\lambda^2 \tag{C14.7.5.3.3-5}$$

$$\lambda = S_i\sqrt{\frac{3G}{K}} \tag{C14.7.5.3.3-6}$$

where:

$K$ = bulk modulus (ksi)
$L$ = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
$W$ = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
$\lambda$ = compressibility index

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)

$n$ = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter $n$ may be increased by one-half for each such exterior layer.

$\theta_s$ = maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.)

The shear strain due to shear deformation of any bearing may be taken as:

$$\gamma_s = \frac{\Delta_s}{h_{rt}} \qquad (14.7.5.3.3\text{-}10)$$

where:

$h_{rt}$ = total elastomer thickness (in.)

$\Delta_s$ = maximum total static or cyclic shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.)

In each case, the static and cyclic components of the shear strain shall be considered separately and then combined using Eq. 14.7.5.3.3-1.

In bearings with externally bonded steel plates on both top and bottom, the peak hydrostatic stress shall satisfy:

$$\sigma_{hyd} \le 2.25G \qquad (14.7.5.3.3\text{-}11)$$

in which:

$$\sigma_{hyd} = 3GS_i^3 \frac{\theta_s}{n} C_\alpha \qquad (14.7.5.3.3\text{-}12)$$

$$C_\alpha = \frac{4}{3}\left[\left(\alpha^2 + \frac{1}{3}\right)^{1.5} - \alpha\left(1-\alpha^2\right)\right] \qquad (14.7.5.3.3\text{-}13)$$

$$\alpha = \frac{\varepsilon_a}{S_i}\frac{n}{\theta_S} \qquad (14.7.5.3.3\text{-}14)$$

$$\varepsilon_a = \frac{\sigma_s}{3B_a G S_i^2} \qquad (14.7.5.3.3\text{-}15)$$

for rectangular bearings:

$$B_a = 1.6 \qquad (14.7.5.3.3\text{-}16)$$

In the absence of better information, the bulk modulus, $K$, may be taken as 450 ksi for all elastomers permissible under this specification for use in steel-reinforced elastomeric bearings.

The compressibility index, $\lambda$, represents the effect of finite bulk stiffness of the rubber. For conventional bearings it makes little difference, but in high shape factor bearings it reduces the stiffness below the value that would be computed using an incompressible model (i.e. with $\lambda = 0$).

Previous editions of these Specifications contained provisions to prevent net upward movement of any point on the bearing. Recent research (Stanton et al., 2007) has shown that, if the bearing is not equipped with bonded external plates, the sole plate can lift away from the bearing without causing any tension in the elastomer. Furthermore, the compression effects are slightly less severe than in a bearing that is identical except for the presence of bonded external plates, and is subjected to the same loading combination. Thus the "no-lift-off" provisions have been removed.

However, in a bearing equipped with external plates, upward movement of part of the plate can cause internal rupture due to hydrostatic tension. Provisions have been added to address this case. It is expected to control only rarely, and when it does, it is likely to do so during construction, when the axial load is light and the rotation, due to pre-camber, is large. For the construction load case, the cyclic components of the loading will be zero. For bearings with external plates, Eqs. 14.7.5.3.3-1 and 14.7.5.3.3-11 should be checked under all critical loading conditions, including construction, and about both strong and weak axes of rectangular bearings when necessary and appropriate.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

and, for circular bearings:

$$B_a = 1.6 \quad (14.7.5.3.3\text{-}17)$$

where:

$B_a$ = dimensionless coefficient used to determine peak hydrostatic stress
$\varepsilon_a$ = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)
$\theta_s$ = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)
$\sigma_s$ = total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

For values of $\alpha$ greater than one-third, the hydrostatic stress is compressive, so Eq. 14.7.5.3.3-11 is satisfied automatically and no further evaluation is necessary.

The constant 1.6 assigned to $B_a$ for rectangular and circular bearings represents a simplified value for determining compressive strain due to a purely axial load (Eq. 14.7.5.3.3-15). This also applies to hydrostatic tension which is evaluated for rotation about an axis, which is parallel to the transverse axis of the bridge. It was derived from procedures suggested by Stanton et al. (2007). A more precise value of $B_a$ (and consequently more precise value of E and axial strain) may alternatively be determined with Eqs. C14.7.5.3.3-7 or C14.7.5.3.3-8 about either primary orthogonal axis.

For rectangular bearings:

$$B_a = \left(2.31 - 1.86\lambda\right) + \left(-0.90 + 0.96\lambda\right) \times \left[1 - \min\left(\frac{L}{W}, \frac{W}{L}\right)\right]^2 \quad (C14.7.5.3.3\text{-}7)$$

and, for circular bearings:

$$B_a = \frac{2}{1 + 2\lambda^2} \quad (C14.7.5.3.3\text{-}8)$$

Tests have shown that sharp edges on the internal steel reinforcement layers cause stress concentrations in the elastomer and promote the onset of debonding. The internal steel reinforcement layers should be deburred or otherwise rounded prior to molding the bearing. The design values in Eq. 14.7.5.3.3-1 are consistent with this procedure.

*14.7.5.3.4—Stability of Elastomeric Bearings*

Bearings shall be investigated for instability at the service limit state load combinations specified in Table 3.4.1-1.

Bearings satisfying Eq. 14.7.5.3.4-1 shall be considered stable, and no further investigation of stability is required.

$$2A \le B \quad (14.7.5.3.4\text{-}1)$$

in which:

$$A = \frac{1.92\frac{h_{rt}}{L}}{\sqrt{1 + \frac{2.0L}{W}}} \quad (14.7.5.3.4\text{-}2)$$

$$B = \frac{2.67}{\left(S_i + 2.0\right)\left(1 + \frac{L}{4.0W}\right)} \quad (14.7.5.3.4\text{-}3)$$

where:

*C14.7.5.3.4*

The average compressive stress is limited to half the predicted buckling stress. The latter is calculated using the buckling theory developed by Gent, modified to account for changes in geometry during compression, and calibrated against experimental results (Gent, 1964; Stanton et al., 1990). This provision will permit taller bearings and reduced shear forces compared to those permitted under the 17th edition of the AASHTO *Standard Specifications for Highway Bridges*.

Eq. 14.7.5.3.4-4 corresponds to buckling in a sideways mode and is relevant for bridges in which the deck is not rigidly fixed against horizontal translation at any point. This may be the case in many bridges for transverse translation perpendicular to the longitudinal axis. If one point on the bridge is fixed against horizontal movement, the sideway buckling mode is not possible, and Eq. 14.7.5.3.4-5 should be used. This freedom to move horizontally should be distinguished from the question of whether the bearing is subject to shear deformations relevant to Articles 14.7.5.3.2 and 14.7.5.3.3. In a bridge

All rights reserved. Duplication is a violation of applicable law.

$G$ = shear modulus of the elastomer (ksi)
$h_{rt}$ = total elastomer thickness (in.)
$L$ = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
$S_i$ = shape factor of the $i$th internal layer of an elastomeric bearing
$W$ = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

For a rectangular bearing where $L$ is greater than $W$, stability shall be investigated by interchanging $L$ and $W$ in Eqs. 14.7.5.3.4-2 and 14.7.5.3.4-3.

For circular bearings, stability may be investigated by using the equations for a square bearing with $W = L = 0.8D$.

For rectangular bearings not satisfying Eq. 14.7.5.3.4-1, the stress due to the total load shall satisfy Eq. 14.7.5.3.4-4 or 14.7.5.3.4-5.

- If the bridge deck is free to translate horizontally:

$$\sigma_s \le \frac{GS_i}{2A - B} \qquad (14.7.5.3.4\text{-}4)$$

- If the bridge deck is fixed against horizontal translation:

$$\sigma_s \le \frac{GS_i}{A - B} \qquad (14.7.5.3.4\text{-}5)$$

that is fixed at one end, the bearings at the other end will be subjected to imposed shear deformation but will not be free to translate in the sense relevant to buckling due to the restraint at the opposite end of the bridge.

A negative or infinite limit from Eq. 14.7.5.3.4-5 indicates that the bearing is stable and is not dependent on $\sigma_s$.

If the value $A - B \le 0$, the bearing is stable and is not dependent on $\sigma_s$.

*14.7.5.3.5—Reinforcement*

The minimum thickness of steel reinforcement, $h_s$, shall be .0625 in., as specified in Article 4.5 of AASHTO M 251.

The thickness of the steel reinforcement, $h_s$, shall satisfy:

- At the service limit state:

$$h_s \ge \frac{3h_{ri}\sigma_s}{F_y} \qquad (14.7.5.3.5\text{-}1)$$

- At the fatigue limit state:

$$h_s \ge \frac{2h_{ri}\sigma_L}{\Delta F_{TH}} \qquad (14.7.5.3.5\text{-}2)$$

where:

$\Delta F_{TH}$ = constant amplitude fatigue threshold for Category A as specified in Article 6.6 (ksi)
$h_{ri}$ = thickness of $i$th internal elastomeric layer (in.)

*C14.7.5.3.5*

The reinforcement should sustain the tensile stresses induced by compression of the bearing. With the present load limitations, the minimum steel plate thickness practical for fabrication will usually provide adequate strength.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$\sigma_L$ = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)
$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)
$F_y$ = yield strength of steel reinforcement (ksi)

If holes exist in the reinforcement, the minimum thickness shall be increased by a factor equal to twice the gross width divided by the net width.

Holes in the reinforcement cause stress concentrations. Their use should be discouraged. The required increase in steel thickness accounts for both the material removed and the stress concentrations around the hole.

*14.7.5.3.6—Compressive Deflection*

Deflections of elastomeric bearings due to dead load and to instantaneous live load alone shall be considered separately.

Loadings considered in this Article shall be at the service limit state with all load factors equal to 1.0.

Instantaneous live load deflection shall be taken as:

$$\delta_L = \sum \varepsilon_{Li} h_{ri} \qquad (14.7.5.3.6\text{-}1)$$

where:

$\varepsilon_{Li}$ = instantaneous live load compressive strain in $i$th elastomer layer
$h_{ri}$ = thickness of $i$th elastomeric layer (in.)

Initial dead load deflection shall be taken as:

$$\delta_d = \sum \varepsilon_{di} h_{ri} \qquad (14.7.5.3.6\text{-}2)$$

where:

$\varepsilon_{di}$ = initial dead load compressive strain in $i$th elastomer layer
$h_{ri}$ = thickness of $i$th elastomeric layer (in.)

Long-term dead load deflection, including the effects of creep, shall be taken as:

$$\delta_{lt} = \delta_d + a_{cr}\delta_d \qquad (14.7.5.3.6\text{-}3)$$

where:

$a_{cr}$ = creep deflection divided by initial dead load deflection

Values for $\varepsilon_{Li}$ and $\varepsilon_{di}$ shall be determined from test results or by analysis. Creep effects should be determined from information relevant to the elastomeric compound used. If the engineer does not elect to obtain a value for the ratio, $a_{cr}$, from test results using Annex A2 of AASHTO M 251, the values given in Table 14.7.6.2-1 may be used.

*C14.7.5.3.6*

Limiting instantaneous live load deflections is important to ensure that deck joints and seals are not damaged. Furthermore, bearings that are too flexible in compression could cause a small step in the road surface at a deck joint when traffic passes from one girder to the other, giving rise to additional impact loading. A maximum relative live load deflection across a joint of 0.125 in. is suggested. Joints and seals that are sensitive to relative deflections may require limits that are tighter than this.

Long-term dead load deflections should be considered where joints and seals between sections of the bridge rest on bearings of different design and when estimating redistribution of forces in continuous bridges caused by settlement.

Laminated elastomeric bearings have a nonlinear load-deflection curve in compression. In the absence of information specific to the particular elastomer to be used, Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may be used as an approximate guide for calculating dead and live load compressive strains for Eqs. 14.7.5.3.6-1 and 14.7.5.3.6-2. It should be noted that as shape factors become higher (greater than ≈6), the correlation of results between Eq. C14.7.5.3.6-1 and Figure C14.7.6.3.3-1 diverges. Eq. C14.7.5.3.6-1 provides a linear solution for a material that exhibits nonlinear behavior in compression. A bearing-specific value of axial strain may be found using Eqs. 14.7.5.3.3-15, C14.7.5.3.3-7 and C14.7.5.3.3-8.

$$\varepsilon = \frac{\sigma}{4.8GS^2} \qquad (C14.7.5.3.6\text{-}1)$$

where:

$\sigma$ = instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi)
$S$ = shape factor of an individual elastomer layer
$G$ = shear modulus of the elastomer (ksi)

Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may also be used as an approximate guide for specifying an allowable value of compressive strain at the design dead plus live

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

service limit state compressive load when employing Section 8.8.1 of AASHTO M 251.

Guidance for specifying an allowable value for creep when Annex A2 of AASHTO M 251 is employed may be obtained from NCHRP Report 449 or from Table 14.7.6.2-1.

Reliable test data on total deflections are rare because of the difficulties in defining the baseline for deflection. However, the change in deflection due to live load can be reliably predicted either by design aids based on test results or by using theoretically based equations (Stanton and Roeder, 1982). In the latter case, it is important to include the effects of bulk compressibility of the elastomer, especially for high shape factor bearings.

*14.7.5.3.7—Seismic and Other Extreme Event Provisions*

*C14.7.5.3.7*

The seismic and other extreme event demands on elastomeric bearings exceed their design limits. Therefore, positive connection between the girder and the substructure concrete is needed. If the bearing is intended to act as a fuse or irreparable damage is permitted, the positive connection need not be designed for the maximum extreme event limit state forces.

Holes in elastomer cause stress concentrations that can lead to tearing of the elastomer during earthquakes.

Elastomeric expansion bearings shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The sole plate and the base plate shall be made wider to accommodate the anchor bolts. Inserts through the elastomer should not be allowed, unless approved by the Engineer. The anchor bolts shall be designed for the combined effect of bending and shear for seismic and other extreme event loads as specified in Article 14.6.5.3. Elastomeric fixed bearings shall be provided with horizontal restraint adequate for the full horizontal load.

**14.7.5.4—Anchorage for Bearings without Bonded External Plates**

In bearings without externally bonded steel plates, a restraint system shall be used to secure the bearing against horizontal movement if:

$$\frac{\theta_s}{n} \geq \frac{3\varepsilon_a}{S_i} \qquad (14.7.5.4\text{-}1)$$

where:

$n$ = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter $n$ may be increased by one-half for each such exterior layer.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$S_i$ = shape factor of the $i$th internal layer of an elastomeric bearing

$\varepsilon_a$ = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

$\theta_s$ = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)

## 14.7.6—Elastomeric Pads and Steel-Reinforced Elastomeric Bearings—Method A

### 14.7.6.1—General

The provisions of this Article shall be taken to apply to the design of:

- Plain elastomeric pads, PEP;
- Pads reinforced with discrete layers of fiberglass, FGP;
- Steel-reinforced elastomeric bearings in which $S_i^2/n < 22$, and for which the primary rotation is about the axis parallel to the transverse axis of the bridge; and
- Cotton-duck pads (CDP) with closely spaced layers of cotton duck and manufactured and tested under compression in accordance with Military Specification MIL-C-882E except where superseded by these Specifications.

where:

$n$ = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter $n$ may be increased by one-half for each such exterior layer.

$S_i$ = shape factor of the $i$th internal layer of an elastomeric bearing

Layer thicknesses in FGP may be different from one another. For steel-reinforced elastomeric bearings designed in accordance with the provisions of this Section, internal layers shall be of the same thickness, and cover layers shall be no more than 70 percent of the thickness of internal layers.

The shape factor for PEP, FGP pads, and steel-reinforced elastomeric bearings covered by this Article shall be determined as specified in Article 14.7.5.1. The shape factor for CDP shall be based upon the total pad thickness.

### C14.7.6.1

Elastomeric pads have characteristics different from those of steel-reinforced elastomeric bearings. Plain elastomeric pads are weaker and more flexible because they are restrained from bulging by friction alone (Roeder and Stanton, 1983 and 1986). Slip inevitably occurs, especially under dynamic loads, causing larger compressive deflections and higher internal strains in the elastomer.

In the fourth edition of the *AASHTO LRFD Bridge Design Specifications*, the stress limits for steel elastomeric bearing pads designed by Method A were increased by 25 percent. This increase was based on the application of Method B equations with an assumed service limit rotation of 0.02 radians to determine the strain effects of rotation and the resulting reserve capacity for axial stresses (Stanton et al., 2007). Therefore, design for rotation in Method A is implicit in the geometric and stress limits given. Since Method A is restricted to bearings pads rotated about their strong axis, a square bearing pad provided the conservative case for determining the increased stress limit. An $S_i^2$/n ratio of 16 was selected for the calculation and resulted in the compressive stress limits of Eqs. 14.7.6.3.2–6 and 14.7.6.3.2–7. For rectangular bearing pads, the specified limit of 22 for $S_i^2/n$ is appropriate except that a limiting value of 20 for $S_i^2/n$ should be considered when the value of $n$ is greater than or equal to 3. A limiting value of 16 should be considered when the bearing pad is circular or nearly square.

In pads reinforced with layers of fiberglass, the reinforcement inhibits the deformations found in plain pads. However, elastomers bond less well to fiberglass, and the fiberglass is weaker than steel, so the fiberglass pad is unable to carry the same loads as a steel-reinforced bearing (Crozier et al., 1979). FGP has the advantage that it can be cut to size from a large sheet of vulcanized material.

CDP are preformed pads that are produced in large sheets and cut to size for specific bridge applications. CDP are reinforced with closely spaced layers of cotton-duck and typically display high compressive stiffness and

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

strength, obtained by the use of very thin elastomeric layers. However, the thin layers also give rise to very high shear and rotational stiffness, which could easily lead to edge loading and a higher shear stiffness than that to be found in layered bearings. These increased shear and rotational stiffnesses lead to larger moments and forces in the bridge and reduced movement and rotational capacity of the bearing pad. As a consequence, CDP is often used with a PTFE slider on top of the elastomer pad (Nordlin et al., 1970).

It is essential that CDP bearing pads be tested and verified to meet the test requirements of Military Specification MIL-C-882E which can be found at https://assist.dla.mil. Note that there is no AASHTO equivalent to this Military Specification. A summary of testing and acceptance criteria for CDP is given below.

These criteria require that:

- A lot of preformed CDP be defined as a single sheet that is continuously formed to a given thickness except that a single lot not exceed 2,500 lbs of material;
- A minimum of two samples from each lot shall be tested;
- The samples be 2 in. × 2 in. with the full sheet thickness;
- The test specimens be cured for four hours at room temperature (70°F ± 10°F);
- Each specimen is then to be loaded in compression, perpendicular to the direction of lamination;
- The origin of deflection and compressive strain measurements be taken at a compressive stress of 5 psi;
- The load be increased at a steady rate of 500 lbs/min. and the deflection be recorded;
- The specimen be loaded to a compressive stress of 10,000 psi without fracture or other failure; and
- The entire lot of CDP be rejected if any of the CDP specimens fail to satisfy either of these test criteria: The average compressive strain of the specimens for that lot is not to be less than 0.075 in./in. nor shall it be greater than 0.175 in./in. at an average compressive stress of 2,000 psi. CDP bearing pads which fail to achieve the 10,000 psi stress limit here fall outside the specified strain range and will not develop the deformation limits permitted in later parts of Article 14.7.

All rights reserved. Duplication is a violation of applicable law.

### 14.7.6.2—Material Properties

The elastomeric-type materials for PEP, FGP, and steel-reinforced elastomeric bearings shall satisfy the requirements of Article 14.7.5.2, except as noted below:

- Hardness on the Shore A scale may be used as a basis for specification of bearing material,
- The specified shear modulus for PEP, FGP, and steel-reinforced elastomeric bearings with a PTFE or equivalent slider on top of the bearing shall be between 0.080 ksi and 0.250 ksi or the nominal hardness shall be between 50 and 70 on the Shore A scale, and
- The specified shear modulus for steel-reinforced elastomeric bearings without a PTFE or equivalent slider on top of the bearing designed in accordance with the provisions of Article 14.7.6 shall be between 0.080 and 0.175 ksi or the nominal hardness shall be between 50 and 60 on the Shore A scale.

PEP, FGP, and steel-reinforced elastomeric bearings with or without a PTFE or equivalent slider on top of the bearing shall conform to the requirements of Article 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251. If the material is specified by its hardness, the shear modulus for design purposes shall be taken as the least favorable value from the range for that hardness given in Table 14.7.6.2-1. Intermediate values may be obtained by interpolation. If the material is specified by shear modulus, it shall be taken for design purposes as the least favorable from the value specified according to the ranges given in Article 14.7.5.2. Other properties, such as creep deflection, are also given in Table 14.7.6.2-1.

The shear force on the structure induced by deformation of the elastomer in PEP, FGP, and steel-reinforced elastomeric bearings shall be based on a $G$ value not less than that of the elastomer at 73°F. Effects of relaxation shall be ignored.

CDP shall be manufactured to Military Standard MIL-C-882E except where the provisions of these Specifications supersede those provisions. The elastomeric-type materials for CDP shall have a nominal hardness between 50 and 70 on the Shore A scale and meet the requirements of Article 14.7.5.2 as appropriate. The finished CDP shall have a nominal hardness between 85 and 95 on the Shore A scale. The shear modulus for CDP may be estimated using Eq. 14.7.6.3.4-3. The cotton-duck reinforcement shall be either a two-ply cotton yarn or a single-ply 50-50 blend cotton–polyester. The fabric shall have a minimum tensile strength of 150 lb./in. width when tested by the grab method. The fill shall be 40 ± 2 threads per in., and the warp shall be 50 ± 1 threads per in. The CDP provisions included herein shall be

### C14.7.6.2

The elastomer requirements for PEP and FGP are the same as those required for steel-reinforced elastomeric bearings. The ranges given in Table 14.7.6.2-1 represent the variations found in practice. If the material is specified by hardness, a safe and presumably different estimate of $G$ should be taken for each of the design calculations, depending on whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. Creep varies from one compound to another and is generally more prevalent in harder elastomers or those with a higher shear modulus but is seldom a problem if high-quality materials are used. This is particularly true because the deflection limits are based on serviceability and are likely to be controlled by live load, rather than total load. The creep values given in Table 14.7.6.2-1 are representative of neoprene and are conservative for natural rubber.

CDP is made of elastomers with hardness and properties similar to that used for PEP and FGP. However, the closely spaced layers of duck fabric reduce the indentation and increase the hardness of the finished pad to the 85 to 95 durometer range. Appendix X1 of AASHTO M 251 contains provisions for hardness of elastomers, but not finished CDP. The acceptable range from the specified value for hardness of elastomers is ±5 points on the Shore A scale. The acceptable range criteria for elastomers in AASHTO M 251 may also be considered for finished CDP. The cotton-duck requirements are restated from the military specification because the reinforcement is essential to the good performance of these pads.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

taken as only applicable to bearing pads up to 2 in. in total thickness.

**Table 14.7.6.2-1—Correlated Material Properties**

| | Hardness (Shore A) | | |
|---|---|---|---|
| | 50 | 60 | 70 [1] |
| Shear Modulus @ 73°F (ksi) | 0.095–0.130 | 0.130–0.200 | 0.200–0.300 |
| Creep deflection @ 25 yr divided by initial deflection | 0.25 | 0.35 | 0.45 |

[1] Only for PEP, FGP, and steel-reinforced elastomeric bearings with a PTFE or equivalent slider on top of the bearing.

### 14.7.6.3—Design Requirements

*14.7.6.3.1—Scope*

Steel-reinforced elastomeric bearings may be designed in accordance with this Article, in which case they qualify for the test requirements appropriate for elastomeric pads. For this purpose, they shall be treated as FGP.

The provisions for FGP apply only to pads where the fiberglass is placed in double layers 0.125 in. apart.

The physical properties of neoprene and natural rubber used in these bearings shall conform to AASHTO M 251.

*C14.7.6.3.1*

The design methods for elastomeric pads are simpler and more conservative than those for steel-reinforced bearings, so the test methods are less stringent than those of Article 14.7.5. Steel-reinforced elastomeric bearings may be made eligible for these less stringent testing procedures by limiting the compressive stress as specified in Article 14.7.6.3.2.

The three types of pad—PEP, FGP, and CDP—behave differently, so information relevant to the particular type of pad should be used for design. For example, in PEP, slip at the interface between the elastomer and the material on which it is seated or loaded is dependent on the friction coefficient, and this will be different for pads seated on concrete, steel, grout, epoxy, etc.

*14.7.6.3.2—Compressive Stress*

At the service limit state, the average compressive stresses, $\sigma_s$ and $\sigma_L$, in any layer shall satisfy:

- For PEP:

$$\sigma_s \le 1.00GS \text{ and} \quad (14.7.6.3.2\text{-}1)$$

$$\sigma_s \le 0.80\,\text{ksi} \quad (14.7.6.3.2\text{-}2)$$

- For FGP:

$$\sigma_s \le 1.25GS_i \text{ and} \quad (14.7.6.3.2\text{-}3)$$

$$\sigma_s \le 1.0\,\text{ksi} \quad (14.7.6.3.2\text{-}4)$$

- For CDP:

$$\sigma_s \le 3.0\,\text{ksi} \text{ and} \quad (14.7.6.3.2\text{-}5)$$

$$\sigma_L \le 2.0\,\text{ksi} \quad (14.7.6.3.2\text{-}6)$$

where:

*C14.7.6.3.2*

In PEP, the compressive stress is limited to $G$ times the shape factor and an absolute limit of 0.80 ksi. A stress check incorporating $G$ times the shape factor limits the use of a proportionately thick PEP with a high compressive stress. In FGP, the compressive stress is limited to $1.25G$ times the effective shape factor and an absolute limit of 1.0 ksi. The CDP stress limits were developed to provide long-term serviceability and durability. CDP stiffness and behavior is less sensitive to shape factor. The total maximum compressive stress is limited to 3.0 ksi because experiments showed that CDP does not fail under monotonically compressive stress values significantly larger than this stress limit. CDP, which is subject to compressive stress levels larger than 3.0 ksi, may delaminate under dynamic loadings typical of those experienced by bridge bearings. CDP may experience dramatic failure when maximum compressive strains exceed approximately 0.25. However, bearing pads which meet the strain and stiffness limits which are required by the military specification will not achieve this failure strain under pure compressive load. The live load stresses are limited to 2.0 ksi, because

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)
$S$ = shape factor for PEP
$\sigma_L$ = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)

In FGP, the value of $S_i$ used shall be based upon an $h_{ri}$ layer thickness which equals the greatest distance between midpoints of two double fiberglass reinforcement layers.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article:

$$\sigma_s \le 1.25GS_i \text{ and} \qquad (14.7.6.3.2\text{-}7)$$

$$\sigma_s \le 1.25 \text{ ksi} \qquad (14.7.6.3.2\text{-}8)$$

where the value of $S_i$ used shall be that of an internal layer of the bearing.

These stress limits may be increased by ten percent where shear deformation is prevented.

In FGP, the value of $S_i$ used shall be based upon an $h_{ri}$ layer thickness that equals the greatest distance between midpoints of two double fiberglass reinforcement layers.

*14.7.6.3.3—Compressive Deflection*

In addition to the provisions of Article 14.7.5.3.6, the following shall also apply.

In lieu of using specific product data, the compressive deflection of a FGP should be taken as 1.5 times the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

The compressive deflection under instantaneous live load and initial dead load of a PEP or an internal layer of a steel-reinforced elastomeric bearing at the service limit state without impact shall not exceed $0.09h_{ri}$, where $h_{ri}$ is the thickness of a PEP, or the thickness of an internal layer of a steel-reinforced elastomeric bearing (in.).

research shows that delamination is caused by the compressive stress range as well as the maximum compressive level. Live loads control the maximum compressive stress range under repeated loading, and this limit controls the adverse effects of this delamination. Larger compressive strains would result in increased damage to the bridge and the bearing pad and reduced serviceability of the CDP (Lehman et al., 2003).

The reduced stress limit for steel-reinforced elastomeric bearings designed in accordance with these provisions is invoked in order to allow these bearings to be eligible for the less stringent test requirements for elastomeric pads.

*C14.7.6.3.3*

The compressive deflection with PEP, FGP, and CDP will be larger and more variable than that of steel-reinforced elastomeric bearings. Appropriate data for these pad types may be used to estimate their deflections. In the absence of such data, the compressive deflection of a PEP and FGP may be estimated at 3 and 1.5 times, respectively, the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

Figure C14.7.6.3.3-1 provides design aids for determining the strain in an elastomer layer for steel-reinforced bearings based upon durometer hardness and shape factor. It should also be noted that initial dead load compressive deflection does not include deflections associated with long-term creep.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

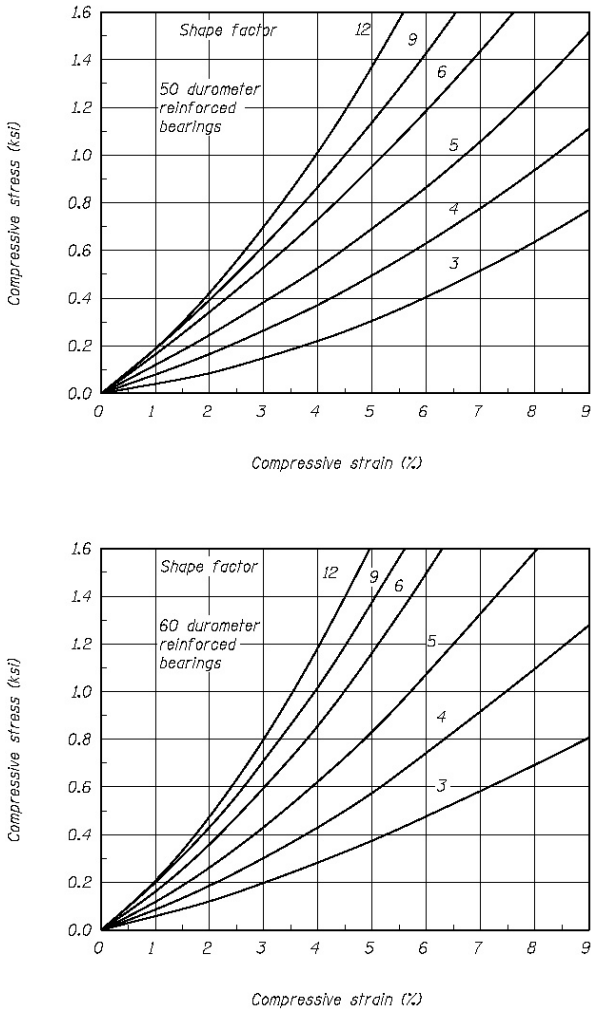

**Figure C14.7.6.3.3-1—Stress-strain Curves**

For CDP, the computed compressive strain, $\varepsilon_s$, may be taken as:

$$\varepsilon_s = \frac{\sigma_s}{E_c} \qquad (14.7.6.3.3\text{-}1)$$

where:

$E_c$ = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)

$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

CDP is typically very stiff in compression. The shape factor may be computed, but it has a different meaning and less significance to the compressive deflection than it does for FGP and PEP (Roeder et al., 2000). As a result, the maximum compressive deflection for CDP can be based upon an average compressive strain, $\varepsilon_s$, for the total bearing pad thickness as computed in Eq. 14.7.6.3.3-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*14.7.6.3.4—Shear*

The maximum horizontal superstructure displacement shall be computed in accordance with Article 14.4. The maximum shear deformation of the pad at the service limit state, $\Delta_S$, shall be taken as the maximum horizontal superstructure displacement, reduced to account for the pier flexibility and modified for construction procedures. If a low friction sliding surface is used, $\Delta_S$ need not be taken to be larger than the deformation corresponding to first slip.

The provisions of Article 14.7.5.3.2 shall apply, except that the pad shall be designed as follows:

- For PEP, FGP and steel-reinforced elastomeric bearings:

$$h_{rt} \geq 2\Delta_S \qquad (14.7.6.3.4\text{-}1)$$

- For CDP:

$$h_{rt} \geq 10\Delta_S \qquad (14.7.6.3.4\text{-}2)$$

where:

$h_{rt}$ = smaller of total elastomer or bearing thickness (in.)

$\Delta_S$ = maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.)

The shear modulus, $G$, for CDP for determination of the bearing force in Article 14.6.3.1 may be conservatively estimated as:

$$G = 2\sigma_s \geq 2.0 \text{ ksi} \qquad (14.7.6.3.4\text{-}3)$$

where:

$\sigma_s$ = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

*C14.7.6.3.4*

The deformation in PEP and FGP are limited to $\pm 0.5\, h_{rt}$ because these movements are the maximum tolerable for repeated and long-term strains in the elastomer. These limits are intended to ensure serviceable bearings with no deterioration of performance and they limit the forces that the pad transmits to the structure.

In CDP, the shear deflection is limited to only one-tenth of the total elastomer thickness. There are several reasons for this limitation. First, experiments show that CDP may split and crack at larger shear strains. Second, CDP has much larger shear stiffness than that noted with steel-reinforced elastomeric bearings, PEP and FGP, and so the strain limit assures that CDP pads do not cause dramatically larger bearing forces to the structure than do other bearing systems. Third, the greater shear stiffness means that relative slip between the CDP and the bridge girders is likely if the deformation required of the bearing is too large. Slip may lead to abrasion and deterioration of the pads, as well as other serviceability concerns. Slip may also lead to increased costs because of anchorage and other requirements. Finally, CDP pads are harder than PEP and FGP, and so they are very suitable for the addition of PTFE sliding surfaces to accommodate the required bridge movements. As a result, CDP with large translational movements is invariably designed with PTFE sliding surfaces.

*14.7.6.3.5—Rotation*

*14.7.6.3.5a—General*

The provisions of these Articles shall apply at the service limit state. Rotations shall be taken as the maximum sum of the effects of initial lack of parallelism and subsequent girder end rotation due to imposed loads and movements. Stress shall be the maximum stress associated with the load conditions inducing the maximum rotation.

*C14.7.6.3.5a*

In the fourth edition of the Specifications, rotation of steel-reinforced elastomeric bearings and elastomeric pads was, in part, controlled by preventing uplift between the bearing and the structure. Research (Stanton et al., 2007) has shown that lift-off is not a concern for elastomeric bearings and the "no lift-off" provisions were removed from Method B as described in Article C14.7.5.3.3. Furthermore, as explained in Article C14.7.6.1, design for rotation in Method A is implicit in the geometric and stress limits given. Therefore, the "no lift-off"

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*14.7.6.3.5b—Rotation of CDP*

The maximum compressive strain due to combined compression and rotation of CDP at the service limit state, $\varepsilon_t$, shall not exceed:

$$\varepsilon_t = \varepsilon_c + \frac{\theta_s L}{2t_p} < 0.20 \qquad (14.7.6.3.5b\text{-}1)$$

where:

$$\varepsilon_c = \frac{\sigma_s}{E_c} \qquad (14.7.6.3.5b\text{-}2)$$

Maximum rotation shall be limited to:

$$\theta_s \le 0.80\frac{2t_p\varepsilon_c}{L} \text{ and} \qquad (14.7.6.3.5b\text{-}3)$$

$$\theta_L \le 0.20\frac{2t_p\varepsilon_c}{L} \qquad (14.7.6.3.5b\text{-}4)$$

where:

$E_c$ = uniaxial compressive stiffness of the CDP bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data
$L$ = length of a CDP bearing pad in the plane of rotation (in.)
$t_p$ = total thickness of CDP pad (in.)
$\varepsilon_c$ = maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1
$\varepsilon_t$ = maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1
$\sigma_s$ = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)
$\theta_L$ = maximum rotation of the CDP pad at the service limit state (load factor = 1.0) due to live load (rad.)
$\theta_s$ = maximum rotation of the CDP pad from the applicable service load combinations in Table 3.4.1-1 (rad.)

provisions have been removed from Method A in order to provide consistency between the two procedures. Additionally, it has been shown that the Method A limit on $S_i^2/n$ (Article 14.7.6.1) prevents the build-up of any significant hydrostatic tension in bearings with bonded external plates.

*C14.7.6.3.5b*

Rotation, and combined compression and rotation of CDP are controlled by shear strain limits and delamination requirements. Experiments show that CDP that meets the testing requirements of MIL-C-882E will not fracture or fail until a combined compressive strain exceeds 0.25. Creep strains do not contribute to this fracture potential. Design Eq. 14.7.6.3.5b-1 limits this compressive strain to 0.20, because the design is made with service loads, and research shows that the 0.20 strain limit is sufficiently far from the average failure strain to assure a β factor of 3.5 for LRFD design. Delamination due to rotation is associated with uplift or separation between the bearing pad and the load surface. Delamination does not result in a fracture or immediate failure of the bearing pad, but it results in a significant reduction in the bearing service life. Cyclic rotation associated with live loads represents the more severe delamination problem, and Eq. 14.7.6.3.5b-4 provides this design limit. However, research also shows that delamination is also influenced by maximum rotation level. CDP do not recover all of their compressive deformation after unloading, and Eq. 14.7.6.3.5b-3 recognizes approximately 20 percent residual compressive strain and limits uplift due to the maximum rotation in recognition of the delamination potential. Shear strains of the elastomer are a less meaningful measure for CDP than for steel reinforced elastomeric bearings, because shape factor has a different meaning for CDP than for other elastomeric bearing types. CDP is known to have relatively large compressive load capacity, and it is generally accepted that it can tolerate relatively large compressive strains associated with these loads. It should be noted that these compressive strains in CDP are larger than those tolerated in steel reinforced bearings, but they have been justified by experimental results for CDP that meets the requirements of these Specifications. This does not suggest that CDP is generally superior to steel-reinforced elastomeric bearings. A well designed steel-reinforced bearing is likely to provide superior long-term performance, but CDP can be designed and manufactured quickly and may provide good performance under a range of conditions.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

*14.7.6.3.6—Stability*

To ensure stability, the total thickness of the pad shall not exceed the least of $L/3$, $W/3$, or $D/4$.

where:

$L$ = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
$n$ = number of interior layers of elastomer, where interior layers are defined as those layers that are bonded on each face. Exterior layers are defined as those layers that are bonded only on one face. When the thickness of the exterior layer of elastomer is more than one half the thickness of an interior layer, the parameter $n$ may be increased by one half for each such exterior layer.
$W$ = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
$D$ = diameter of pad (in.)

*C14.7.6.3.6*

The stability provisions in this Article are unlikely to have a significant impact upon the design of PEP, since a plain pad which has this geometry would have such a low allowable stress limit that the design would be uneconomical.

The buckling behavior of FGP and CDP is complicated because the mechanics of their behavior is not well understood. The reinforcement layers lack the stiffness of the reinforcement layers in steel-reinforced bearings and so stability theories developed for steel-reinforced bearings do not apply to CDP or FGP. The geometric limits included here are simple and conservative.

*14.7.6.3.7—Reinforcement*

The reinforcement in FGP shall be fiberglass with a strength in each plan direction of at least 2.2 $h_{ri}$ in kip/in. For the purpose of this Article, if the layers of elastomer are of different thicknesses, $h_{ri}$ shall be taken as the mean thickness of the two layers of the elastomer bonded to the same reinforcement. If the fiberglass reinforcement contains holes, its strength shall be increased over the minimum value specified herein by twice the gross width divided by net width.

Reinforcement for steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article shall conform to the requirements of Article 14.7.5.3.5.

*C14.7.6.3.7*

The reinforcement should be strong enough to sustain the stresses induced in it when the bearing is loaded in compression. For a given compression, thicker elastomer layers lead to higher tension stresses in the reinforcement. It should be possible to relate the minimum reinforcement strength to the compressive stress that is allowed in the bearing in Article 14.7.6.3.2. The relationship has been quantified for FGP. For PEP and CDP, successful past experience is the only guide currently available.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of Article 14.7.6, the equations from Article 14.7.5.3.5 are used. Although these equations are intended for steel-reinforced bearings with a higher allowable stress, the thickness of reinforcing sheets required is not significantly greater than those required by the old Method A.

*14.7.6.3.8—Seismic and Other Extreme Event Provisions*

Expansion bearings designed according to Article 14.7.6 shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The provisions of Article 14.7.5.3.7 shall also apply as applicable.

## 14.7.7—Bronze or Copper Alloy Sliding Surfaces

### 14.7.7.1—Materials

Bronze or copper alloy may be used for:

- flat sliding surfaces to accommodate translational movements,
- curved sliding surfaces to accommodate translation and limited rotation, and
- pins or cylinders for shaft bushings of rocker bearings or other bearings with large rotations.

Bronze sliding surfaces or castings shall conform to ASTM B22 and shall be made of Alloy C90500, C91100, or C86300, unless otherwise specified. The mating surface shall be structural steel, which has a Brinell hardness value at least 100 points greater than that of the bronze.

### C14.7.7.1

Bronze or copper alloy sliding surfaces have a long history of application in the United States with relatively satisfactory performance of the different materials. However, there is virtually no research to substantiate the properties and characteristics of these bearings. Successful past experience is the best guide currently available.

Historically these bearings have been built from sintered bronze, lubricated bronze, or copper alloy with no distinction between the performance of the different materials. However, the evidence suggests otherwise. Sintered bronze bridge bearings have historically been included in the Standard Specifications. Sintered bronze is manufactured with a metal powder technology, which results in a porous surface structure that is usually filled with a self-lubricating material. There do not appear to be many manufacturers of sintered bronze bridge bearings at this time, and there is some evidence that past bridge bearings of this type have not always performed well. As a result, there is no reference to sintered bronze herein.

Lubricated bronze bearings are produced by a number of manufacturers, and they have a relatively good history of performance. The lubrication is forced into a pattern of recesses, and the lubrication reduces the friction and prolongs the life of the bearing. Plain bronze or copper lacks this self-lubricating quality and would appear to have poorer bearing performance. Some jurisdictions use the following guidelines for lubricant recesses (FHWA, 1991):

- The bearing surfaces should have lubricant recesses consisting of either concentric rings, with or without central circular recesses with a depth at least equal to the width of the rings or recesses.
- The recesses or rings should be arranged in a geometric pattern so that adjacent rows overlap in the direction of motion.
- The entire area of all bearing surfaces that have provision for relative motion should be lubricated by means of the lubricant-filled recesses.
- The lubricant-filled areas should comprise not less than 25 percent of the total bearing surface.
- The lubricating compound should be integrally molded at high pressure and compressed into the rings or recesses and project not less than 0.010 in. above the surrounding bronze plate.

All rights reserved. Duplication is a violation of applicable law.

Bronze or copper alloy sliding expansion bearings shall be evaluated for shear capacity and stability under lateral loads.

The mating surface shall be made of steel and be machined to match the geometry of the bronze surface so as to provide uniform bearing and contact.

Bronze or copper-alloy sliding expansion bearings should be evaluated for stability. The sliding plates inset into the metal of the pedestals or sole plates may lift during high horizontal loading. Guidelines for bearing stability evaluations may be found in Gilstad (1990). The shear capacity and stability may be increased by adding anchor bolts inserted through a wider sole plate and set in concrete.

The mating surface is commonly manufactured by a steel fabricator rather than by the bearing manufacturer who produces the bronze surface. This contractual arrangement is discouraged because it can lead to a poor fit between the two components. The bronze is weaker and softer than the steel, and fracture and excessive wear of the bronze may occur if there is inadequate quality control.

#### 14.7.7.2—Coefficient of Friction

The coefficient of friction may be determined by testing. In lieu of such test data, the design coefficient of friction may be taken as 0.1 for self-lubricating bronze components and 0.4 for other types.

#### C14.7.7.2

The best available experimental evidence suggests that lubricated bronze can achieve a coefficient of friction on the order of 0.07 during its early life, while the lubricant projects above the bronze surface. The coefficient of friction is likely to increase to approximately 0.10 after the surface lubrication wears away and the bronze starts to wear down into the recessed lubricant. Copper alloy or plain bronze would cause considerably higher friction. In the absence of better information, conservative coefficients of friction of 0.1 and 0.4, respectively, are recommended for design.

#### 14.7.7.3—Limit on Load

The nominal bearing stress due to combined dead and live load at the service limit state shall not exceed the values given in Table 14.7.7.3-1.

**Table 14.7.7.3-1—Bearing Stress at the Service Limit State**

| ASTM B22 Bronze Alloy | Bearing Stress (ksi) |
|---|---|
| C90500—Type 1 | 2.0 |
| C91100—Type 2 | 2.0 |
| C86300—Type 3 | 8.0 |

#### 14.7.7.4—Clearances and Mating Surfaces

The mating surface shall be steel that is accurately machined to match the geometry of the bronze surface and to provide uniform bearing and contact.

### 14.7.8—Disc Bearings

#### 14.7.8.1—General

The dimensions of the elements of a disc bearing shall be such that hard contact between metal components, which prevents further displacement or rotation, will not occur under the least favorable combination of design

#### C14.7.8.1

A disc bearing functions by deformation of a polyether urethane disc, which should be stiff enough to resist vertical loads without excessive deformation and yet be flexible enough to accommodate the imposed rotations

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

displacements and rotations at the strength limit state.

The disc bearing shall be designed for the maximum strength limit state design rotation, $\theta_u$, specified in Article 14.4.2.2.2.

For the purpose of establishing the forces and deformations imposed on a disc bearing, the axis of rotation may be taken as lying in the horizontal plane at midheight of the disc. The urethane disc shall be held in place by a positive location device.

Limiting rings may be used to partially confine the elastomer against lateral expansion. They may consist of steel rings welded to the upper and lower plates or a circular recess in each of those plates.

If a limiting ring is used, the depth of the ring should be at least $0.03D_d$, where $D_d$ is the diameter of the disk element.

without liftoff or excessive stress on other components, such as PTFE. The urethane disc should be positively located to prevent its slipping out of place.

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

$\theta_u$ may also be considered at the extreme event limit state.

The depth of the limiting ring should be at least $0.03D_d$ to prevent possible overriding by the urethane disc under extreme rotation conditions.

### 14.7.8.2—Materials

The elastomeric disc shall be made from a compound based on polyether urethane, using only virgin materials. The hardness shall be between 45 and 65 on the Shore D scale.

The metal components of the bearing shall be made from structural steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709M), Grade 36, 50, or 50W or from stainless steel conforming to ASTM A240.

### C14.7.8.2

AASHTO *LRFD Bridge Construction Specifications*, Article 18.3.2, provides material specifications for polyether urethane compounds.

Polyether urethane can be compounded to provide a wide range of hardnesses. The appropriate material properties must be selected as an integral part of the design process because the softest urethanes may require a limiting ring to prevent excessive compressive deflection, whereas the hardest ones may be too stiff and cause too high a resisting moment. Also, harder elastomers generally have higher ratios of creep to elastic deformation.

AASHTO M 270M/M 270 (ASTM A709/A709M), Grades 100 and 100W steel should be used only where their reduced ductility will not be detrimental.

### 14.7.8.3—Elastomeric Disc

The elastomeric disc shall be held in location by a positive locator device.

At the service limit state, the disc shall be designed so that:

- its instantaneous deflection under total load does not exceed ten percent of the thickness of the unstressed disc, and the additional deflection due to creep does not exceed eight percent of the thickness of the unstressed disc;
- the components of the bearing do not lift off each other at any location; and
- the average compressive stress on the disc does not exceed 5.0 ksi. If the outer surface of the disc is not vertical, the stress shall be computed using the smallest plan area of the disc.

### C14.7.8.3

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

Design of the urethane disc may be based on the assumption that it behaves as a linear elastic material, unrestrained laterally at its top and bottom surfaces. The estimates of resisting moments, so calculated, will be conservative, because they ignore creep, which reduces the moments. However, the compressive deflection due to creep should also be accounted for. Limiting rings stiffen the bearing in compression because they make the bearing behave more like a confined elastomeric bearing, i.e., a pot bearing. Their influence is conservatively ignored in the linear elastic design approach. Subject to the approval of the Engineer, design methods based on test data are permitted.

No liftoff of components can be tolerated; therefore, any uplift restraint device should have sufficiently small

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

If a PTFE slider is used, the stresses on the PTFE slider shall not exceed the values for average and edge stresses given in Article 14.7.2.4 for the service limit state. The effect of moments induced by the urethane disc shall be included in the stress analysis.

vertical slack to ensure the correct location of all components when the compressive load is reapplied.

Rotational experiments have shown that uplift occurs at relatively small moments and rotations in disc bearings. There are concerns that this could lead to edge loading on PTFE sliding surfaces and increase the potential for damage to the PTFE. Bearings passing the test requirements of Article 18.3.4.4.4 of the AASHTO *LRFD Bridge Construction Specifications* should assure against any damage to the PTFE.

#### 14.7.8.4—Shear Resisting Mechanism

In fixed and guided bearings, a shear-resisting mechanism shall be provided to transmit horizontal forces between the upper and lower steel plates. It shall be capable of resisting a horizontal force in any direction equal to the larger of the design shear force at the strength and extreme event limit states or 15 percent of the design vertical load at the service limit state.

The horizontal design clearance between the upper and lower components of the shear-restricting mechanism shall not exceed the value for guide bars given in Article 14.7.9.

#### C14.7.8.4

The shear-resisting device may be placed either inside or outside the urethane disc. If shear is carried by a separate transfer device external to the bearing, such as opposing concrete blocks, the bearing itself may be unguided.

In unguided bearings, the shear force that should be transmitted through the body of the bearing is $\mu P$, where $\mu$ is the coefficient of friction of the PTFE slider and $P$ is the vertical load on the bearing. This may be carried by the urethane disc without a separate shear-resisting device, provided that the disc is held in place by positive locating devices, such as recesses in the top and bottom plates.

The 15 percent factor applied to the service limit state vertical load approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

#### 14.7.8.5—Steel Plates

The provisions of Sections 3, 4, and 6 of these Specifications shall apply as appropriate.

The thickness of each of the upper and lower steel plates shall not be less than 0.045 $D_d$, where $D_d$ is the diameter of the disk element, if it is in direct contact with a steel girder or distribution plate, or 0.06 $D_d$ if it bears directly on grout or concrete.

#### C14.7.8.5

The plates should be thick enough to uniformly distribute the concentrated load in the bearing. Distribution plates should be designed in accordance with Article 14.8.

### 14.7.9—Guides and Restraints

#### 14.7.9.1—General

Guides may be used to prevent movement in one direction. Restraints may be used to permit only limited movement in one or more directions. Guides and restraints shall have a low-friction material at their sliding contact surfaces.

#### C14.7.9.1

Guides are frequently required to control the direction of movement of a bearing. If the horizontal force becomes too large to be carried reliably and economically on a guided bearing, a separate guide system may be used.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 14.7.9.2—Design Loads

Guides or restraints shall be designed at the strength limit state for:

- the horizontal force from applicable strength load combinations specified in Table 3.4.1-1, but shall not be taken less than
- 15 percent of the total vertical force from applicable service load combinations specified in Table 3.4.1-1 acting on all the bearings at the bent divided by the number of guided bearings at the bent.

Guides and restraints shall be designed for applicable seismic or other extreme event forces using the extreme event limit state load combinations of Table 3.4.1-1 and, in the case of seismic, the provisions in Article 3.10.9.

### C14.7.9.2

The 15 percent factor applied to the service limit state vertical load approximates a minimum strength limit state horizontal design force. This design force is intended to account for responses that cannot be calculated reliably, such as horizontal bending or twisting of a bridge deck caused by nonuniform or time-dependent thermal effects.

Large ratios of horizontal to vertical load can lead to bearing instability, in which case a separate guide system should be considered.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

### 14.7.9.3—Materials

For steel bearings, the guide or restraint shall be made from steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709M), Grades 36, 50, or 50W or stainless steel conforming to ASTM A240. For aluminum bearings, the guide may also be aluminum.

The low-friction interface material shall be approved by the Engineer.

### C14.7.9.3

Many different low-friction materials have been used in the past. Because the total transverse force at a bent is usually smaller than the total vertical force, the guides may contribute less toward the total longitudinal friction force than the primary sliding surfaces. Thus, material may be used that is more robust but causes higher friction than the primary material. Filled PTFE is common, and other proprietary materials, such as PTFE-impregnated metals, have proven effective.

### 14.7.9.4—Geometric Requirements

Guides shall be parallel, long enough to accommodate the full design displacement of the bearing in the sliding direction, and shall permit a minimum of 0.03125 in. and a maximum of 0.0625 in. free slip in the restrained direction. Guides shall be designed to avoid binding under all design loads and displacements, including rotation.

### C14.7.9.4

Guides must be parallel to avoid binding and inducing longitudinal resistance. The clearances in the transverse direction are fairly tight and are intended to ensure that excessive slack does not exist in the system. Free transverse slip has the advantage that transverse restraint forces are not induced, but if this is the objective a nonguided bearing is preferable. On the other hand, if applied transverse loads are intended to be shared among several bearings, free slip causes the load to be distributed unevenly, possibly leading to overloading of one guide.

### 14.7.9.5—Design Basis

#### *14.7.9.5.1—Load Location*

The horizontal force acting on the guide or restraint shall be assumed to act at the centroid of the low-friction interface material. Design of the connection between the guide or restraint and the body of the bearing system shall consider both shear and the overturning moments so caused.

#### *C14.7.9.5.1*

Guides are often bolted to the slider plate to avoid welding distortions. Horizontal forces applied to the guide cause some overturning moment, which must be resisted by the bolts in addition to shear. The tension in the bolt can be reduced by using a wider guide bar. If high-strength bolts are used, the threaded hole in the plate should be deep enough to develop the full tensile strength of the bolt.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The design and detailing of bearing components resisting lateral loads, including seismic and other extreme event loads determined as specified in Article 14.6.3.1, shall provide adequate strength and ductility. Guide bars and keeper rings or nuts at the ends of pins and similar devices shall either be designed to resist all imposed loads or an alternative load path shall be provided that engages before the relative movement of the substructure and superstructure is excessive.

Some press-fit guide bar details in common use have proven unsatisfactory in resisting horizontal loads. When analyzing such designs, consideration should be given to the possibility of rolling the bar in the recess (SCEF, 1991).

Where guide bars are recessed into a machined slot, tolerances should be specified to provide a press fit. The guide bar should also be welded or bolted to resist overturning.

Past earthquakes have shown that guide and keeper bars and keeper rings or nuts at the ends of pins and other guiding devices have failed, even under moderate seismic loads. In an experimental investigation of the strength and deformation characteristics of rocker bearings (Mander et al., 1993), it was found that adequately sized pintles are sometimes capable of providing the necessary resistance to seismic loads.

*14.7.9.5.2—Contact Stress*

*C14.7.9.5.2*

The contact stress on the low-friction material shall not exceed that recommended by the manufacturer. For PTFE, the stresses at the service limit state shall not exceed those specified in Table 14.7.2.4-1 under sustained loading or 1.25 times those stresses for short-term loading.

Appropriate compressive stresses for proprietary materials should be developed by the Manufacturer and approved by the Engineer on the basis of test evidence. Strength, cold flow, wear, and friction coefficient should be taken into consideration.

On conventional materials, higher stresses are allowed for short-term loading because the limitations in Table 14.7.2.4-1 are based partly on creep considerations. Short-term loading includes wind, earthquake, etc., but not thermal or gravity effects.

**14.7.9.6—Attachment of Low-Friction Material**

**C14.7.9.6**

The low-friction material shall be attached by at least any two of the following three methods:

- mechanical fastening,
- bonding, and
- mechanical interlocking with a metal substrate.

Some difficulties have been experienced where PTFE is attached to the metal backing plates by bonding alone. Ultra-violet light attacks the PTFE surface that is etched prior to bonding, and this has caused bond failures. Thus, at least two separate methods of attachment are required. Mechanical fasteners should be countersunk to avoid gouging the mating surface.

**14.7.10—Other Bearing Systems**

**C14.7.10**

Bearing systems made from components not specified in Articles 14.7.1 through 14.7.9 may also be used, subject to the approval of the Engineer. Such bearings shall be adequate to resist the forces and deformations imposed on them at the service and strength limit states without material distress and without inducing deformations detrimental to their proper functioning. At the extreme event limit state, bearings which are designed to act as fuses or sustain irreparable damage may be permitted by the Owner provided loss of span is prevented.

The dimensions of the bearing shall be chosen to provide for adequate movements at all times. Materials

Tests cannot be prescribed unless the nature of the bearing is known. In appraising an alternative bearing system, the Engineer should plan the test program carefully because the tests constitute a larger part of the quality assurance program than is the case with more widely used bearings.

In bearings that rely on elastomeric components, aspects of behavior, such as time-dependent effects, response to cyclic loading, temperature sensitivity, etc., should be investigated.

Some bearing tests are very costly to perform. Other bearing tests cannot be performed because there is no

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

shall have sufficient strength, stiffness, and resistance to creep and decay to ensure the proper functioning of the bearing throughout the design life of the bridge.

The Engineer shall determine the tests that the bearing shall satisfy. The tests shall be designed to demonstrate any potential weakness in the system under individual compressive, shear, or rotational loading or combinations thereof. Testing under sustained and cyclic loading shall be required.

available test equipment in the United States. At the present time, the largest U.S. facility for testing bearings in combined axial load and shear is the Seismic Response Modification Device Test Facility at the University of California, San Diego constructed by Caltrans. This facility can test bearings of all kinds up to 12,000-kip axial load capacity and 2,000-kip transverse load capacity (HITEC, 2002). Nevertheless, the following test requirements should be carefully considered before specifying them (SCEF, 1991):

- Vertical loads exceeding 5,000 kips,
- Horizontal loads exceeding 500 kips,
- The simultaneous application of horizontal and vertical load where the horizontal load exceeds 75 percent of the vertical load,
- Triaxial test loading,
- The requirement for dynamic rotation of the test bearing while under vertical load, and
- Coefficient of friction test movements with normal loads greater than 250 kips.

## 14.8—LOAD PLATES AND ANCHORAGE FOR BEARINGS

### 14.8.1—Plates for Load Distribution

The bearing, together with any additional plates, shall be designed so that:

- The combined system is stiff enough to prevent distortions of the bearing that would impair its proper functioning when subjected to service and strength limit state loadings, and maximum extreme event loadings when required;
- The stresses imposed on the supporting structure satisfy the limits specified by the Engineer and Sections 5, 6, 7, or 8; and
- The bearing can be replaced within the jacking height limits specified by the Engineer without damage to the bearing, distribution plates, or supporting structure. If no limit is given, a height of 0.375 in. shall be used.

Resistance of steel components shall be determined in accordance with Section 6.

**C14.8.1**

Large forces may be concentrated in a bearing that must be distributed so as not to damage the supporting structure. In general, metal rocker and roller bearings cause the most concentrated loads, followed by pots, discs, and sphericals, whereas elastomeric bearings cause the least concentrated loads. Masonry plates may be required to prevent damage to concrete or grout surfaces.

Many simplified methods have been used to design masonry plates, some based on strength and some on stiffness. Several studies have indicated that masonry plates are less effective in distributing the load than these simplified methods would suggest, but the cost of heavy load distribution plates would be considerable (McEwen and Spencer, 1981; Saxena and McEwen, 1986). The present design rules represent an attempt to provide a uniform basis for design that lies within the range of traditional methods. Design based on more precise information, such as finite element analysis, is preferable but may not be practical in many cases.

In lieu of a more refined analysis, the load from a bearing fully supported by a grout bed may be assumed to distribute at a slope of 1.5:1, horizontal to vertical, from the edge of the smallest element of the bearing that resists the compressive load.

The use and design of bearing stiffeners on steel girders shall comply with Section 6.

Sole plate and base plate connections shall be adequate to resist lateral loads at the strength limit state. These connections shall also be adequate to resist the maximum seismic and other extreme event lateral loads unless the bearings are designed to act as fuses or sustain irreparable damage. Sole plates shall be extended to allow for anchor bolt inserts, when required.

One common way to provide for replacement is to use a masonry plate, attached to the concrete pier head by embedded anchors or anchor bolts. The bearing can then be attached to the masonry plate by seating it in a machined recess and bolting it down. The bridge needs then to be lifted only through a height equal to the depth of the recess in order to replace the bearing. The deformation tolerance of joints and seals, as well as the stresses in the structure, should be considered in determining the allowable jacking height.

### 14.8.2—Tapered Plates

If, under full permanent load at the mean annual temperature for the bridge site (at the service limit state with all load factors equal to 1.0), the inclination of the underside of the girder to the horizontal exceeds 0.01 rad., a tapered plate shall be used in order to provide a level surface.

### C14.8.2

Tapered plates may be used to counteract the effects of end slope in a girder. In all but short-span bridges, the dead load will dominate the forces on the bearing, so the tapered plate should be designed to provide zero rotation of the girder under this condition. The limit of 0.01 rad. out of level corresponds to the 0.01 rad. component, which is required in the design rotation in Article 14.4.

### 14.8.3—Anchorage and Anchor Bolts

#### 14.8.3.1—General

All load distribution plates and bearings with external steel plates shall be positively secured to their associated superstructure or substructure element by bolting or welding.

All girders shall be positively secured to supporting bearings by a connection that can resist the horizontal forces that may be imposed on it unless fusing or irreparable damage is permitted at the extreme event limit state. Separation of bearing components shall not be permitted at the strength limit state. Connections shall resist the least favorable combination of loads at the strength limit state and shall be installed wherever deemed necessary to prevent separation.

Trusses, girders, and rolled beams shall be securely anchored to the substructure. Where possible, anchor bolts should be cast in substructure concrete, otherwise anchor bolts may be grouted in place. Anchor bolts may be swedged or threaded to secure a satisfactory grip upon the material used to embed them in the holes.

The resistance of the anchor bolts shall be adequate for loads at the strength limit state and for the maximum loads at the extreme event limit state unless the bearings

#### C14.8.3.1

Bearings should be anchored securely to the support to prevent their moving out of place during construction or over the life of the bridge. Elastomeric bearings may be left without anchorage if adequate friction is available. A design coefficient of friction of 0.2 may be assumed between elastomer and clean concrete or steel.

Girders may be located on bearings by bolts or pintles. The latter provide no uplift capacity. Welding may be used, provided that it does not cause damage to the bearing or difficulties with replacement.

Uplift should be prevented both among the major elements, such as the girder, bearing, and support, and between the individual components of a bearing. If uplift occurs, some parts of the structure could be misaligned when contact is regained, causing damage.

Anchor bolts are very susceptible to brittle failure during earthquakes or other extreme events. To increase ductility, it has been recommended in Astaneh-Asl et al. (1994) to use upset anchor bolts placed inside hollow sleeve pipes and oversized holes in the masonry plate. Thus, deformable bearing types may use the anchor bolts as the ductile element (Cook and Klingner, 1992).

Bearings designed for rigid load transfer, especially at the extreme event limit state, should not be seated on

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

are designed to act as fuses or sustain irreparable damage.

The tensile resistance of anchor bolts shall be determined as specified in Article 6.13.2.10.2.

The shear resistance of anchor bolts and dowels shall be determined as specified in Article 6.13.2.12.

The resistance of anchor bolts in combined tension and shear shall be determined as specified in Article 6.13.2.11.

The bearing resistance of the concrete shall be taken as specified in Article 5.6.5. The modification factor, *m*, shall be based on a nonuniformly distributed bearing stress.

grout pads or other bedding materials that can create a sliding surface and reduce the horizontal resistance.

Seismic loading of the anchor bolts has often resulted in concrete damage, especially when they were too close to the edge of the bearing seat. Guidelines for evaluating edge distance effects and concrete strength requirements may be found in Ueda et al. (1990), among others.

For global design of anchorages to concrete, refer to *Building Code Requirements for Structural Concrete* (ACI 318-05), Appendix D.

As an approximation, the bearing stress may be assumed to vary linearly from zero at the end of the embedded length to its maximum value at the top surface of concrete.

#### 14.8.3.2—Seismic and Other Extreme Event Design and Detailing Requirements

Sufficient reinforcement shall be provided around the anchor bolts to develop the level of horizontal forces considered at the extreme event limit state and anchor them into the mass of the substructure unit. Potential concrete crack surfaces next to the bearing anchorage shall be identified and their shear friction capacity evaluated as required.

## 14.9—CORROSION PROTECTION

All exposed steel parts of bearings not made from stainless steel shall be protected against corrosion by zinc metalization, hot-dip galvanizing, or a paint system approved by the Engineer. A combination of zinc metalization or hot-dip galvanizing and a paint system may be used.

## C14.9

The use of stainless steel is the most reliable protection against corrosion because coatings of any sort are subject to damage by wear or mechanical impact. This is particularly important in bearings where metal-to-metal contact is inevitable, such as rocker and roller bearings. Weathering steel is excluded because it forms an oxide coating that may inhibit the proper functioning of the bearing.

When using hot-dip galvanizing for corrosion protection, several factors must be considered. Embrittlement of very high-strength fasteners, such as ASTM A490 bolts, may occur due to acid cleaning (pickling) before galvanizing, and quenched and tempered material, such as Grade 70W and 100W, may undergo changes in mechanical properties, so galvanizing these should be avoided (see ASTM A143 on avoiding embrittlement). With good practice, commonly used steels, such as Grades 36, 50, and 50W, should not be adversely affected if their chemistry and the assembly's details are compatible (see ASTM A385 on ensuring high-quality coating). Certain types of bearings, such as intricate pot or spherical bearings, are not suitable for hot-dip galvanizing.

SECTION 15

# DESIGN OF SOUND BARRIERS

## 15.1—SCOPE

This Section applies to the structural design of sound barriers which are either ground-mounted or structure-mounted and the design of the foundations of ground-mounted sound barriers.

**C15.1**

This Section specifies the design forces and the design requirements unique to sound barriers constructed along highways. This Section does not cover sound barriers constructed adjacent to railroad tracks or the acoustical requirements for sound barriers.

These provisions are largely based on the requirements of the *Guide Specifications for Structural Design of Sound Barriers* (1989).

## 15.2—DEFINITIONS

*Clear Zone*—The total roadside border area, starting at the edge of the traveled way, available for safe use by errant vehicles.

*Crashworthy*—A traffic railing system that has been successfully crash-tested to a currently acceptable crash test matrix and test level or one that can be geometrically and structurally evaluated as equal to a crash-tested system.

*Ground-Mounted Sound Barriers*—Sound barriers supported on shallow or deep foundations.

*Post-and-Panel Construction*—Type of sound barrier construction consisting of vertical posts supported on a structure or on the foundations and panels spanning horizontally between adjacent posts.

*Right-of-Way*—The land on which a roadway and its associated facilities and appurtenances are located. The highway right-of-way is owned and maintained by the agency having jurisdiction over that specific roadway.

*Right-of-Way Line*—The boundary of the right-of-way.

*Sound Barrier*—A wall constructed along a highway to lower the highway noise level in the area behind the wall.

*Sound Barrier Setback*—The distance between the point on the traffic face of the sound barrier wall that is closest to traffic and the closest point on the traffic face of the traffic railing the sound barrier is mounted on or located behind as defined in Article 15.8.4.

*Structure-Mounted Sound Barriers*—Sound barriers supported on bridges, crashworthy traffic railings, or retaining walls.

*Traffic Railing*—Synonymous with vehicular railing; used as a bridge- or structure-mounted railing rather than as a guardrail or median barrier, as in other publications.

*Vehicular Railing*—Synonymous with traffic railing; used as a bridge- or structure-mounted railing rather than as a guardrail or median barrier, as in other publications.

## 15.3—NOTATION

$S$ = setback distance of sound barrier (15.8.4)
$\varphi$ = soil angle of internal friction (degrees) (C15.4.2)
$\gamma_p$ = load factor for permanent loads (15.9.9)

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

## 15.4—GENERAL FEATURES

### 15.4.1—Functional Requirements

#### 15.4.1.1—General

Consult a roadway professional for sight-distance and sound barrier height and length requirements.

#### 15.4.1.2—Lateral Clearance

Unless dictated by site conditions and approved by the Owner, sound barriers shall be located outside the clear zone or, when the clear zone is wider than the distance between the edge of the traffic lanes and the edge of the available right-of-way, just inside the right-of-way.

**C15.4.1.2**

Locating the sound barrier farther from the edge of the traffic lanes reduces the possibility of vehicular collision with the barrier. The most desirable location for a sound barrier is outside the clear zone, which minimizes the possibility of vehicular collision. In many cases, because sound barriers are typically used in urban areas, the width of available right-of-way is less than the width of the clear zone.

When conditions make it impractical to locate the sound barrier at adequate distance from the edge of traffic lanes and the sound barrier is mounted on a traffic barrier, the recommended minimum clearance from the edge of traffic lanes to the face of the traffic barrier is 10.0 ft. Lateral clearances greater than 10.0 ft should be used when feasible. Guardrail or other traffic barriers should be considered for use when the sound barrier is located inside the clear zone.

In addition to safety considerations, maintenance requirements should be considered in deciding sound barrier locations. Sound barriers placed within the area between the shoulder and right-of-way line complicate the ongoing maintenance and landscaping operations and lead to increased costs, especially if landscaping is placed on both sides of the sound barrier. Special consideration should be given to maintaining the adjoining land behind the sound barrier and adjacent to the right-of-way line.

### 15.4.2—Drainage

Adequate drainage shall be provided along sound barriers.

**C15.4.2**

It is important to have drainage facilities along sound barriers to ensure soil stability. Soils with an angle of internal friction, $\varphi$, of 25 degrees or less may develop flowing characteristics when saturated. Limits on fines, especially clay and peat, should be specified.

### 15.4.3—Emergency Responder and Maintenance Access

Provisions for emergency and maintenance access shall be provided. Local fire department requirements for fire hose and emergency access shall be satisfied.

**C15.4.3**

Provisions may be necessary to allow firefighters and hazardous material clean-up crews access to fire hydrants on the opposite side of the sound barrier. The designer should consult with local fire and emergency officials regarding their specific needs.

Shorter barriers may be traversed by throwing the fire hose over the wall. Taller barriers may require an opening through which the hose is passed. Such an opening can consist of a formed or cored hole, a hollow masonry block turned on its side, a maintenance access

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

gate, etc. A small sign may be placed adjacent to the emergency access location on the traffic side of the sound barrier. This sign would bear the street name on which the hydrant is located, thus aiding emergency crews in identifying the hydrant nearest the opening.

Access to the back side of the sound barrier must be provided if the area is to be maintained. In subdivision areas, access can be via local streets, when available. If access is not available via local streets, access gates or openings are essential at intervals along the sound barrier. Offset barriers concealing the access opening must be overlapped a minimum of 2.5 times the offset distance in order to maintain the integrity of the main barrier's sound attenuation. Location of the access openings should be coordinated with the appropriate agency or land owner.

### 15.4.4—Differential Settlement of Foundations

For long masonry sound barriers supported on spread footings, provisions should be made to accommodate differential settlement.

**C15.4.4**

Provisions should be made to accommodate differential settlement when sound barriers are supported on continuous spread or trench footings or cap beams.

## 15.5—LIMIT STATES AND RESISTANCE FACTORS

### 15.5.1—General

Structural components shall be proportioned to satisfy the requirements at all appropriate service, strength, and extreme event limit states.

Limit states applicable to sound barrier foundation design shall be in accordance with Article 15.9. Limit states applicable to the structural design of sound barrier components shall be as presented herein.

The limit states shall apply using the applicable load combinations in Table 3.4.1-1 and the loads specified herein.

Where masonry or other proprietary walls are utilized, the Owner shall approve the design specifications to be used.

**C15.5.1**

These Specifications do not include design provisions for masonry structures. Design provisions for masonry structures should be taken from other specifications.

### 15.5.2—Service Limit State

The resistance factors for the service limit states for post, wall panel, and foundation components shall be as specified in Article 1.3.2.1. Design for service limit states shall be in accordance with the applicable requirements of Articles 5.5.2, 6.5.2, 7.5.1, and 8.5.1.

### 15.5.3—Strength Limit State

The resistance factors for the strength limit states for post, wall panel, and foundation components shall be as specified in Articles 5.5.4, 6.5.4, 7.5.4, and 8.5.2.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 15.5.4—Extreme Event Limit State

The resistance factors for the extreme event limit states for post, wall panel, and foundation components shall be as specified in Article 1.3.2.1.

## 15.6—EXPANSION DEVICES

### 15.6.1—General

Adequate noise sealant material shall be placed at expansion joints of sound barriers.

### 15.6.2—Structure-Mounted Sound Barriers

Except for post-and-panel construction, as a minimum, expansion joints shall be provided in the sound barriers at the location of expansion joints in the supporting structure, at bridge intermediate supports, and at the centerline of bridge spans.

When post-and-panel construction is utilized, wall panels may be allowed to bridge the expansion joints in, or at the ends of, the deck of the supporting structure where the panels' seat width on the posts is sufficient to accommodate the expansion joint movements and the dimensional and installation tolerances; otherwise, posts shall be placed on either side of any expansion joint in the supporting structure.

### C15.6.2

When the type of construction utilized for sound barriers does not inherently allow movements between the sound barrier components, allowance should be made to accommodate the movement and deformations of the supporting structure. Therefore, expansion devices are required in the sound barriers at expansion joint locations in order not to restrict the movement of the expansion joints of the supporting structures.

Sound barriers mounted on bridges stiffen the supporting bridge superstructures, resulting in longitudinal stresses developing in the sound barriers. The higher curvature of bridge girders at high moment locations near midspans and, for continuous bridges, at intermediate supports increases the magnitude of these stresses. Providing expansion joints in the sound barriers at these locations reduces the effect of the stiffness of the sound barrier on the deformations of the girders and the stresses in the barrier due to live load deflection of the bridge.

When mounted on bridges, additional expansion devices in the sound barrier may be utilized as required to further minimize the stresses on the barrier due to the live load deflection of the bridge.

Post-and-panel sound barriers inherently provide an expansion joint at either end of each wall panel. Typical posts are made of steel rolled I-shapes or concrete I-sections. Characteristically, the seat width of the wall panels on the posts is relatively small as it corresponds to the width of the post flange overhang on either side of the post web. These typical seat widths provide for dimensional and installation tolerances and dimensional changes caused by panel deformations due to applied loads and temperature changes. For smaller post flange widths, unless a post is provided on either side of an expansion joint in the supporting structure, the change in the opening of the structure expansion joint may be larger than the panel seat width on the post and may cause the failure of the panel straddling the structure expansion joint due to the loss of panel seat width.

### 15.6.3—Ground-Mounted Sound Barriers

Except for post-and-panel construction, expansion devices shall be provided at adequate spacing to allow for thermal expansion of the sound barriers. For sound

### C15.6.3

For sound barriers not utilizing post-and-panel construction, minimizing the relative deflection between the wall sections on either side of an expansion joint

barriers prone to vehicular collision, relative deflection between the sound barriers on either side of an expansion joint shall be restricted.

improves the performance of the barrier during vehicular collision near the expansion joint. This can be accomplished by installing a sliding dowel-and-sleeve connection, similar to the one shown in Figure C15.6.3-1, near the top of the wall.

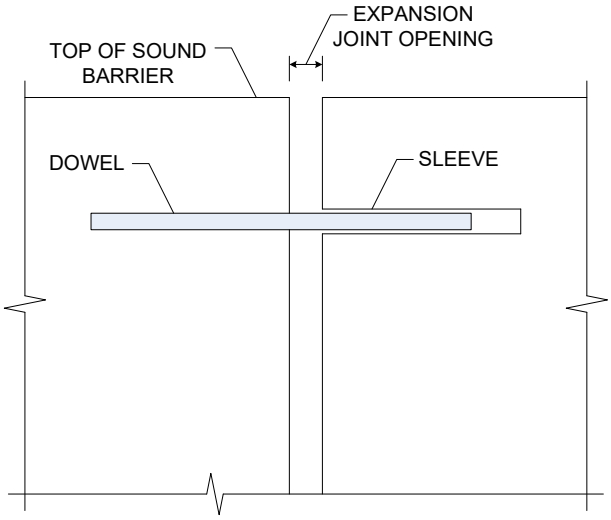

**Figure C15.6.3-1—Sliding Dowel-and-Sleeve Connection**

## 15.7—SOUND BARRIERS INSTALLED ON EXISTING BRIDGES

When sound barriers are installed on existing bridges, the effects of the sound barrier forces on existing bridge components shall be investigated, including the effect of unbalanced mass.

**C15.7**

Sound barrier forces transmitted to the bridge include the weight of the barrier, wind loads, seismic loads, vehicular collision forces, and any other forces that may act on the sound barriers. These forces affect railings, bridge deck overhangs, floorbeams, and girders.

When sound barriers are added on an existing bridge, the bridge should be reanalyzed to determine its load rating taking into account the forces applied to the sound barriers. The stiffening effect of the sound barriers may be considered when determining the load rating of the bridge.

## 15.8—LOADS

### 15.8.1—General

Unless explicitly modified below, all applicable loads shall be applied in accordance with the provisions of Section 3.

### 15.8.2—Wind Load

The provisions of Article 3.8.1 shall apply.

**C15.8.2**

The wind load provisions included in Article 3.8.1 are applicable to all structures, including sound barriers. This deviates from earlier specifications where special wind provisions for sound barriers were included.

### 15.8.3—Earth Load

The provisions of Article 3.11 shall apply.

**C15.8.3**

Article 3.11.5.10 contains specific requirements for the determination of earth pressure on sound foundation components.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

The possibility of difference between the actual finished grade and that shown on the contract documents should be considered in the design.

Soil build-up against sound barriers has been observed in some locations. Owners may determine the earth loads for the worst load case assuming an allowance in the finished grade elevation.

### 15.8.4—Vehicular Collision Forces

### C15.8.4

Sound barrier systems consisting of a traffic railing and a sound barrier that have been successfully crash-tested may be used with no further analysis.

The depth of aesthetic treatments into the traffic face of sound barrier that may be subjected to vehicular collision shall be kept to a minimum.

Minimizing the depth of aesthetic treatment into the traffic face of sound barriers that may be in contact with a vehicle during a collision reduces the possibility of vehicle snagging.

Sound barrier materials shall be selected to limit shattering of the sound barrier during vehicular collision.

Sound barrier systems may contain sacrificial components or components that could need repair after vehicular collision. Limiting shattering of sound barriers is particularly important for sound barriers mounted on bridges crossing over other traffic. When reinforced concrete panels are utilized for structure-mounted sound barriers, it is recommended that two mats of reinforcement are used to reduce the possibility of the concrete shattering during vehicular collision. Restraint cables placed in the middle of concrete panels may be used to reduce shattering while avoiding the increased panel thickness required to accommodate two layers of reinforcement.

The bridge overhang or moment slabs need not be designed for more force effects than the resistance of the base connection of the sound barrier.

In lieu of crash-testing, the resistance of components and connections to Extreme Event II force effects may be determined based on a controlled failure scenario with a load path and sacrificial elements selected to ensure desirable performance of a structural system containing the soundwall. Vehicular collision forces shall be applied to sound barriers located within the clear zone as follows:

The design strategy involving a controlled failure scenario is similar in concept to the use of capacity protected design to resist seismic forces. Some damage to the soundwall, traffic barrier, or connections is often preferable to designing an overhang or moment slab for force effects due to vehicular collision. The bridge overhang or moment slabs need not be designed for more force effects than the resistance of the base connection of the sound barriers.

Some guidance on desirable structural performance of sound barriers can be found in European Standard EN1794-2 (2003).

Very limited information is available on crash-testing of sound barrier systems. The requirements of this Article, including the magnitude of collision forces, are mostly based on engineering judgment and observations made during crash-testing of traffic railings without sound barriers.

In the absence of crash test results for sound barrier systems, sound barriers that have not been crash-tested are often used in conjunction with vehicular railings that have been crash-tested as stand-alone railings, i.e. without sound barriers. The collision forces specified herein are meant to be applied to the sound barrier portion of such systems.

Crash Test Levels 3 and lower are performed using small automobiles and pick-up trucks. Crash Test Levels 4 and higher include single-unit, tractor-trailer trucks, or

**Case 1:** For sound barriers on a crashworthy traffic railing and for sound barriers mounted behind a crashworthy traffic railing with a sound barrier setback no more than 1.0 ft: vehicular collision forces specified in Section 13 shall be applied to the sound barrier at a point 4.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 3 and lower and 6.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 4 and higher.

**Case 2:** For sound barriers behind a crashworthy traffic railing with a sound barrier setback of 4.0 ft: vehicular collision force of 4.0 kips shall be applied. The collision force shall be assumed to act at a point 4.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 3 and lower and 14.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 4 and higher.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

**Case 3:** For sound barriers behind a crashworthy traffic railing with a sound barrier setback between 1.0 ft and 4.0 ft: vehicular collision forces and the point of application of the force shall vary linearly between their values and locations specified in Case 1 and Case 2 above.

**Case 4:** For sound barriers behind a crashworthy traffic railing with a sound barrier setback more than 4.0 ft: vehicular collision forces need not be considered.

The setback of the sound barrier, *S*, shall be taken as shown in Figure 15.8.4-1.

both. The difference in height of the two groups of vehicles is the reason the location of the collision force is different at different Test Levels.

For crash Test Levels 3 and lower, the point of application of the collision force on the sound barriers is assumed to be always 4.0 ft above the pavement.

During crash-testing of traffic railings for crash Test Level 4 and higher, trucks tend to tilt above the top of the railing and the top of the truck cargo box may reach approximately 4.0 ft behind the traffic face of the traffic railing. For such systems, the point of application of the collision force is expected to be as high as the height of the cargo box of a truck, assumed to be 14.0 ft above the pavement surface.

For sound barriers mounted on crashworthy traffic barriers or with a small setback assumed to be less than 1.0 ft, the full crash force is expected to act on the sound barrier. The point of application of this force is assumed to be at the level of the cargo bed, taken as 6.0 ft above the surface of the pavement.

For a sound barrier mounted with a setback more than 1.0 ft behind the traffic face of the traffic railing, it is expected that the truck cargo box, not the cargo bed, will impact the sound barrier. It is expected that the top of the cargo box will touch the sound barrier first. Due to the soft construction of cargo boxes, it is assumed that they will be crushed and will soften the collision with the sound barrier. The depth of the crushed area will increase with the increase of the collision force, thus lowering the location of the resultant of the collision force. The magnitude of the collision force and the degree to which the cargo box is crushed are expected to decrease as the setback of the sound barrier increases.

In the absence of test results, it is assumed that a collision force of 4.0 kips will develop at the top of the cargo box when it impacts sound barriers mounted with a setback of 4.0 ft.

The collision force and the point of application are assumed to vary linearly as the sound barrier setback varies between 1.0 ft and 4.0 ft.

All rights reserved. Duplication is a violation of applicable law.

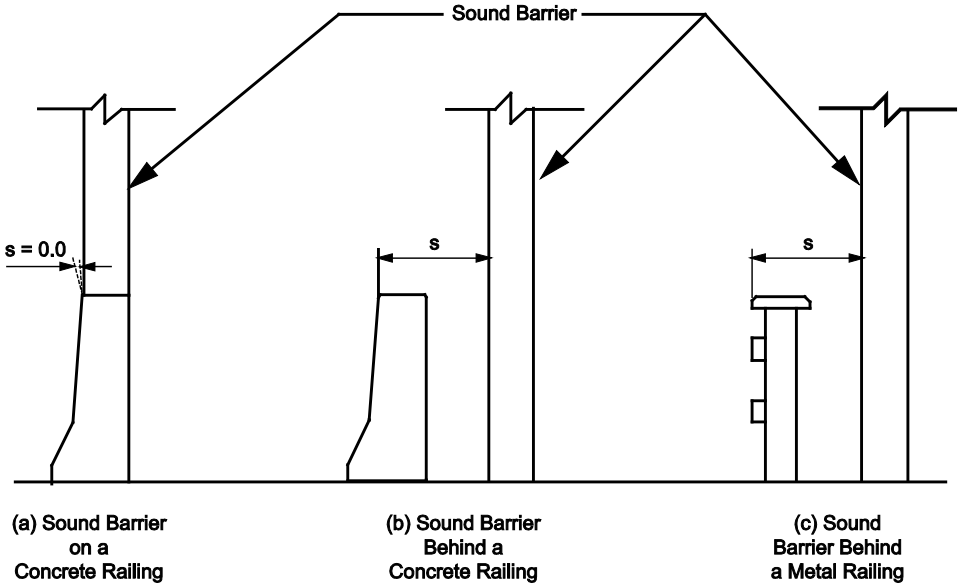

**Figure 15.8.4-1—Sound Barrier Setback Distance**

Collision forces on sound barriers shall be applied as a line load with a length equal to the longitudinal length of distribution of collision forces, $L_t$, specified in Appendix A13.

For sound barriers prone to vehicular collision forces, the wall panels and posts and the post connections to the supporting traffic barriers or footings shall be designed to resist the vehicular collision forces at the Extreme Event II limit state.

For post-and-panel construction, the design collision force for the wall panels shall be the full specified collision force placed on one panel between two posts at the location that maximizes the load effect being checked. For posts and post connections to the supporting components, the design collision force shall be the full specified collision force applied at the point of application specified earlier in Cases 1 through 3.

The vehicular railing part of the sound barrier/railing system does not need to satisfy any additional requirements beyond the requirements specified in Section 13 of these Specifications for the stand-alone railings, including the height and resistance requirements.

Unless otherwise specified by the Owner, vehicular collision forces shall be considered in the design of sound barriers.

In some cases, the wall panel is divided into a series of horizontal elements. In these situations, each horizontal strip should be designed for the full design force.

Owners may elect to ignore vehicular collision forces in the design of sound barriers at locations where the collapse of the sound barrier or portions of thereof has minimal safety consequences.

## 15.9—FOUNDATION DESIGN

### 15.9.1—General

Unless otherwise specified by the Owner, the geotechnical resistance of materials supporting sound barrier foundations shall be estimated using the procedures presented in Article 10.6 for spread footings, Article 10.7 for driven piles, and Article 10.8 for drilled shafts.

**C15.9.1**

Although sound barriers may be supported on spread footing or driven pile foundations, drilled shafts are more commonly used because drilled shafts facilitate controlling the vertical alignment of sound barrier structural wall supports and the lateral spacing between

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 15.9.2—Determination of Soil and Rock Properties

The provisions of Articles 2.4 and 10.4 shall apply.

### 15.9.3—Limit States

Sound barriers shall be designed to withstand lateral wind and earth pressures, self-weight of the wall, vehicular collision loads, and earthquake loads in accordance with the general principles specified in this Section and in Sections 10 and 11.

Sound barriers shall be investigated for vertical and lateral displacement at the Service I Limit State. Tolerable deformation criteria shall be developed based on maintaining the required barrier functionality, achieving the anticipated service life, and the consequences of unacceptable movements.

Sound barrier foundations shall be investigated at the strength limit states using Eq. 1.3.2.1-1 for:

- Bearing-resistance failure,
- Overall stability, and
- Structural failure.

Sound barrier foundations shall be investigated at the extreme event limit states using the applicable load combinations and load factors specified in Table 3.4.1-1.

### 15.9.4—Resistance Requirements

The factored resistance, $R_R$, calculated for each applicable limit state shall be the nominal resistance, $R_n$, multiplied by an appropriate resistance factor, $\phi$, specified in Articles 10.5.5.1, 10.5.5.2, 10.5.5.3, 11.5.6, or 11.5.7.

**C15.9.4**

Procedures for calculating nominal geotechnical resistance of footings, driven piles, and drilled shafts are provided in Articles 10.6, 10.7, and 10.8. These methods are generally accepted for barriers supported on spread footings or footings on two or more rows of driven piles or drilled shafts. The nominal geotechnical resistance of a single row of driven piles or drilled shafts or by a continuous embedded foundation wall (commonly referred to as a "trench footing") is more appropriately calculated using the provisions in Article 11.8 for nongravity cantilever walls.

Procedures for calculating nominal structural resistance for concrete and steel components are provided in Sections 5 and 6.

### 15.9.5—Resistance Factors

The resistance factors for geotechnical design of foundations shall be as specified in Table 10.5.5.2.2-1 for spread footing foundations, Table 10.5.5.2.3-1 for driven pile foundations, Table 10.5.5.2.4-1 for drilled shaft foundations, and Table 11.5.7-1 for permanent retaining walls.

If methods other than those prescribed in these Specifications are used to estimate geotechnical resistance, the resistance factors chosen shall provide reliability equal or greater than those given in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and 11.5.7-1.

© 2020 by the American Association of State Highway and Transportation Officials.
All rights reserved. Duplication is a violation of applicable law.

### 15.9.6—Loading

The provisions of Section 3, as modified by Article 15.8, shall apply.

### 15.9.7—Movement at the Service Limit State

The provisions of Articles 10.6.2, 10.7.2, 10.8.2, or 11.8.3, as appropriate, shall apply.

### 15.9.8—Safety against Geotechnical Failure at the Strength Limit State

Spread footings or footings supported on two or more rows of driven piles or drilled shafts shall be designed in accordance with the provisions of Articles 10.6.3, 10.7.3, or 10.8.3, respectively.

Footings supported on a single row of driven piles or drilled shafts or on a continuous embedded foundation wall ("trench footing") shall be designed in accordance with the provisions of Article 11.8.4 using the earth pressure diagrams provided in Article 3.11.5.10.

For overall stability, the provisions of Article 11.6.3.7 shall apply.

### 15.9.9—Seismic Design

The effect of earthquake loading shall be investigated using the Extreme Event I limit state of Table 3.4.1-1 with load factor $\gamma_p = 1.0$, and an accepted methodology.

### 15.9.10—Corrosion Protection

The provisions of Article 11.8.7 shall apply.

### 15.9.11—Drainage

Where sound barriers support earth loads or can impede water flow, the provisions of Article 11.8.8 shall apply.
